## S1. Protein crystallization

Crystals of equine spleen apoferritin (Sigma, catalogue no. A-3641) were grown in hanging drops consisting of 2 ml of protein at $10 \mathrm{mg} \mathrm{ml}^{-1}$ in 0.1 M sodium acetate buffer pH 6.5 and 2 ml of a well solution consisting of $2 \%(\mathrm{w} / \mathrm{v}) \mathrm{CdSO}_{4}$ and $15 \%(\mathrm{w} / \mathrm{v})\left(\mathrm{NH}_{4}\right)_{2} \mathrm{SO}_{4}$ in the same buffer. Cubic crystals in space group F432 grew to dimensions of $300-500 \mu \mathrm{~m}$ within one week.

Crystals of thaumatin (Sigma, catalogue no. T7638) were grown in hanging drops comprised of equal volumes of protein at $40 \mathrm{mg} \mathrm{ml}^{-1}$ in 0.1 M sodium acetate buffer pH 6.5 and a well solution consisting of $14 \%(\mathrm{w} / \mathrm{v})$ potassium sodium tartrate in the same buffer. Tetragonal crystals in space group $\mathrm{P} 4_{1} 2_{1} 2$ grew to dimensions of $200-300 \mu \mathrm{~m}$ within one week.

Crystals of lysozyme (Sigma, catalogue no. L6876) were grown in hanging drops comprised of equal volumes of protein at $80 \mathrm{mg} \mathrm{ml}^{-1}$ in 0.1 M sodium acetate buffer pH 5.2 and a well solution consisting of $2.5 \%(\mathrm{w} / \mathrm{v}) \mathrm{NaCl}$ in the same buffer. Tetragonal crystals in space group $\mathrm{P} 4_{3} 2_{1} 2_{1}$ grew to dimensions of $300-800 \mu \mathrm{~m}$. Crystals appeared within one week and stopped growing within four weeks.

## S2. Identification of ice diffraction peaks

Ice diffraction peaks associated with individual ice crystals were identified removing protein Bragg peaks from the diffraction frames and then looking for high count pixels near the expected ice ring positions. Potential protein Bragg peaks were masked within a 6-pixel radius circle based on peak locations reported in the XDS output file XDS_ASCII.HKL. Low resolution Bragg peaks and Bragg peaks near the beam stop shadow, rotational axis, and detector panel segments were occasionally excluded in the XDS output file. Regions corresponding to resolutions numerically larger than $10 \AA$, near the beam stop shadow, along the rotational axis and within 15 pixels of the segment edges were thus masked. pyFAI's separate program (Ashiotis et al., 2015) was used to remove Bragg peaks from each diffraction image by azimuthal median filtering and then backfilling the pixels associated with the Bragg peaks. All images in the data set were then averaged to produce a mean background image. This background was linearly scaled (multiplied by a constant) to match each frame. Pixels with intensities larger than five times the scaled mean background were identified as outliers, and a histogram of the number of these pixel observations binned against resolution was constructed. The histograms used a bin spacing of $0.01 \AA$, and the pixel observations were normalized by the total number of such pixels per degree of crystal rotation angle to facilitate comparison of histograms between data sets. Table 1 lists the resolutions of the 11 diffraction rings of hexagonal ice, where ice diffraction peaks should be located, based on 100 K unit cell parameters of $\mathrm{a}=4.497 \AA, \mathrm{~b}=7.322 \AA$ (Fortes, 2018).

## S3. IRRMC data sets analyzed for ice type

The 22 IRRMC data sets analyzed in Section 2.4 for ice type by fitting using a mixture of cubic and hexagonal ice or models of stacking disordered ice were all recorded on Dectris Pilatus 6M detectors. Of these data sets, 14 were recorded using beamline BL11-1 at SSRL, 4 using beamline BL12-2 at SSRL, 2 using beamline 19-ID at APS, 1 using beamline 5.0.1 at ALS and 1 using beamline I04-1 at Diamond. These 22 data sets include the 13 data sets used by (Parkhurst et al., 2017). All contained clear visual evidence of ice diffraction.

## S4. Ice crystallite size determination

## S4.1. Scherrer's constant

The apparent crystallite size in Scherrer's equation is related to the actual crystallite size, $p$, (the cube root of the crystal volume) by $p=K \delta$. The proportionality constant $K$ is known as Scherrer's constant (Langford \& Wilson, 1978), and depends on crystallite shape, crystal symmetry, Miller index and the definition of peak breadth. Scherrer's constant for a cubic crystal's (100), (110), and (111) reflections are $1.0000,1.0607$, and 1.1547 respectively (Langford \& Wilson, 1978). $K$ is assumed to be 1 for this analysis.

## S4.2. Hexagonal ice calibrant

The hexagonal ice sample was generated in situ at the F1 CHESS station as follows. First, a 30\% $\mathrm{w} / \mathrm{w}$ polypropylene glycol 425 solution in a $500 \mu \mathrm{~m}$ diameter PET tube was abruptly cooled to $\mathrm{T}=200$ K by unshuttering a cold gas stream. Abrupt cooling to a temperature where the ice nucleation rate was high resulted in an ideal powder pattern with a large width (indicating a small crystallite size) and having a stacking disordered intensity profile. As this sample was slowly warmed, the intensity profile evolved from stacking disordered to purely hexagonal (Kuhs et al., 2012) and the peak breadths decreased (Figure S3). Above 250 K , the uniformity of the diffraction rings was lost, and each ring eventually broke up into a collection of individual Bragg peaks. The diffraction pattern recorded at 250 K (Figure S4(a)), before the loss of ring uniformity, was used to estimate the instrumental broadening.

The use of this ice sample as a calibrant does not correct broadening due to uncertainty in the experimental geometry, specifically in the assumed beam center and angle between the incident X-ray beam direction and detector normal; these modify the apparent angle of each ice peak and thus the apparent angular width. Estimates of these parameters were improved by adjusting their values to minimize the sum of the breadths of all observed ice rings. For the hexagonal calibrant, this yielded a detector tilt of $0.1^{\circ}$ from the incident X-ray beam normal. The calibrant's corrected breadths are shown
in Figure S4 (b) and have an average of $0.037^{\circ}$. This breadth was then taken as an estimate of the instrumental broadening due to the incident X -ray beam divergence and energy dispersion.

The broadening due to beam divergence and energy dispersion were independently estimated for comparison. Beam divergence $\alpha$ adds linearly to the peak widths, $\Delta 2 \theta \approx \alpha$. Broadening due to beam dispersion is estimated from Bragg's Law through uncertainty propagation,

$$
\begin{aligned}
\Delta 2 \theta & \approx 2 \frac{1}{\sqrt{1-(\lambda / 2 d)^{2}}} \frac{\lambda}{2 d} \frac{\Delta \lambda}{\lambda} . \\
& \approx 2 \cdot \tan (\theta) \frac{\Delta \lambda}{\lambda}
\end{aligned}
$$

For the F1 station, the beam divergence $\alpha=0.028^{\circ}$, and the dispersion $\Delta \lambda / \lambda=0.00173$ corresponds to a broadening of $0.027^{\circ}$. The observed hexagonal ice peaks of the calibrant sample appeared Gaussian, indicating these two factors should add in quadrature. This gives a combined broadening of $0.04^{\circ}$, on par with the measured peak breadth of $0.037^{\circ}$.

## S4.3. Number of ice crystallites required for continuous diffraction rings

The minimum number of ice crystallites required to generate azimuthally continuous diffraction rings can be estimated from the illuminated sample volume and the incident beam divergence. This estimate can in turn be used to set a bound on the crystallite size. Assuming the ice has a sufficiently large grain size that its Bragg peaks have a breadth in the azimuthal direction determined solely by the beam divergence, $\alpha$, the peak's arc length is

$$
\Delta=F \tan (\alpha) .
$$

$F$ is the sample-to-detector distance. The circumference of the diffraction ring is

$$
L=2 \pi F \tan (2 \theta) .
$$

If placed end to end, the number of crystallites needed to generate a complete diffraction ring is $N \approx L / \Delta$. This is multiplied by 10 to ensure there is significant overlap between the Bragg peaks to give

$$
N \approx 10 \cdot 2 \pi \frac{\tan (2 \theta)}{\tan (\alpha)}
$$

This corresponds to 74,000 crystallites for a diffraction peak at $2 \theta=30^{\circ}$ and a measured beam divergence of $\alpha=0.028^{\circ}$ for the CHESS station used in our experiments on apoferritin, thaumatin and lysozyme. For a $100 \mu \mathrm{~m}$ diameter beam and a $500 \mu \mathrm{~m}$ path length, the illuminated volume is $V \approx 3.9 \cdot 10^{6}$ $\mu \mathrm{m}^{3}$. Dividing this total volume by 74,000 gives an upper bound on the crystallite volume of $53 \mu \mathrm{~m}^{3}$
or, assuming a spherical crystallite, a diameter of $4.6 \mu \mathrm{~m}$. This crystallite size gives a finite-size broadening of $\beta \approx 0.0013^{\circ}, 45$ times smaller than the observed hexagonal ice peak breadth, suggesting that the observed peak breadth is limited by the instrumental broadening, as assumed in this estimate.

## S4.4. Source broadening subtraction

The broadening of the observed (detector angle and beam-stop position corrected) ice diffraction peaks is a convolution of the intrinsic and instrumental broadenings. The increase in breadth of a peak following a convolution depends on the shape of the functions involved. For convolutions of Gaussians, the resulting profile is Gaussian, and the breadths add in quadrature; for Lorentzians, the breadths add linearly. The convolution of a Gaussian with a breadth of $\beta_{\text {gauss }}$ and a Lorentzian width a breadth of $\beta_{l o r}$ is a Voight profile with a breadth of (Olivero \& Longbothum, 1977)

$$
\beta_{\text {voigt }} \approx 0.5346 \beta_{\text {lor }}+\sqrt{0.2166 \beta_{\text {lor }}^{2}+\beta_{\text {gauss }}^{2}} .
$$

Peak profiles of the hexagonal ice calibrant were best modelled by Gaussians and are likely dominated by instrumental factors. Peak profiles for ice internal to the protein crystals were best modelled by Lorentzians. This implies that the intrinsic broadening from crystallite size and shape is not Gaussian. While we cannot be certain of its shape, we assumed it is Lorentzian because it is the dominant broadening factor. In this case, the observed breadths are $\beta_{\text {voigt }}$, the instrumental broadening estimated from the hexagonal calibrant peaks is $\beta_{\text {gauss }}$, and the desired breadth of the internal ice with instrumental effects deconvolved is $\beta_{l o r}$ and is given by

$$
\beta_{\text {lor }} \approx \frac{\beta_{\text {voigt }}^{2}-\beta_{\text {gaus }}^{2}}{\beta_{\text {voigt }}} .
$$

## S4.5. Size estimate of ice crystals contributing to outlier pixels

A lower bound on the size of an ice crystal that contributes to a single pixel outlier was calculated with Scherrer's equation using the angular breadth of a single pixel. For a diffraction image recorded at a sample-to-detector distance of $F$, wavelength of $\lambda$ and pixel size $\mu$, the angle subtended by a single pixel is

$$
\beta=\tan ^{-1}((N+1) \mu / F)-\tan ^{-1}(N \mu / F) .
$$

Given a diffraction angle of $\theta, N$ is the radial distance of the outlier pixel from the detector's beam center location in units of pixels

$$
N=\frac{F}{\mu} \tan (2 \theta) .
$$

The breadth can be used in Scherrer's equation to determine a lower bound on the crystallite size as

$$
\delta=\frac{\lambda}{\beta \cdot \cos (\theta)}
$$

Using $F=500 \mathrm{~mm}, \quad \mu=0.172 \mathrm{~mm}$ and $\lambda=1 \AA$, the crystallite size for the (112) hexagonal ice peak at $1.916 \AA$ resolution is $\sim 4,000 \AA$.

## S5. Ice Detection from structure factors

## S5.1. Ice identification only at three locations

This choice to focus on the three ice ring locations common to all forms of ice, rather than all 11 locations of hexagonal ice, improved the robustness of the interpolations through the ice rings and from the $0.01 \AA^{-1}$ to $0.0025 \AA^{-1}$ bins. After binning the values in $0.01 \AA^{-1}$ bins, the bins near the ice peak locations are excluded from further consideration, and the remaining bins are used to interpolate through these excluded regions. As the total number of regions where ice is being searched for increases, more regions need to be interpolated through but there are fewer neighbouring bins to guide the interpolation. Using all 11 ice ring locations often led to erroneous interpolations; interpolations were improved by focusing on the three ice ring locations common to all ice forms. In the case of cubic-like or stacking disordered ice, only ice diffraction at these three locations tends to be strong enough to bias the values, so there is no down-side to this choice. Hexagonal ice produces much narrower and taller peaks at all locations that strongly bias the values, so ice is easily detectable even when only three locations are examined.

## S5.2. Comparison between Ice Finder, Depletion and Observation scores

The Ice Finder Score, Depletion Score and Observation score could be used independently to predict the presence of ice biasing in a data set. This section demonstrates that a combination of these scores performs better than a single score. The weighted average of the maximum IFS and $D S$ were calculated for each entry in the training data set and Generalized Extreme Value Distributions were fit to these sets of weighted averages. These distributions were used to predict the presence of ice in the 200 entry test set used by Thorn et al. and our 200 entry ground truth test set. Table S6 shows the number of false negatives and positives for each of these analyses. A combined metric, $p_{\text {ice }}$, to flag a data set as biased by ice outperformed the metrics on their own.

Figure S1 Collection of X-ray diffraction data from cryocooled glycerol / water solutions. Samples were prepared by injecting $\sim 10 \mathrm{nl}$ of solution into a $250 \mu \mathrm{~m}$ diameter, $\sim 2 \mathrm{~cm}$ long thin-walled polyester tube. The length of tubing filled with solution was approximately $200 \mu \mathrm{~m}$. The tube was then affixed to a goniometer base (Mitegen GB-B1A) and centered in the X-ray beam.

Hexagonal + Cubic Mixture

Figure S2 Left: Theoretical X-ray diffraction patterns for different types of ice generated using DIFFaX. Vertical lines show the (hkl) indices for hexagonal ice. The different types of ice are: (a) pure hexagonal, (b) pure cubic, (c) 50/50 mixture of pure hexagonal and pure cubic ice, (d) stacking disordered ice with $75 \%$ hexagonal stacking and $25 \%$ cubic stacking, (e) stacking disordered ice with $50 \%$ hexagonal and cubic stackings, (f) stacking disordered ice with $25 \%$ hexagonal stacking and $75 \%$ cubic stacking. Right: 2D visualizations of the different types of ice and how they stack. Hexagonal ice, cubic ice, and stacking disordered ice are made of two different types of atomic planes and only differ in how the planes stack. Hexagonal ice is an alternate stacking of the two atomic planes. Cubic ice can be made from either plane by shifting successive planes in the stack by $1 / 3$ of the unit cell. In stacking disordered ice, the two types of planes stack randomly.

Figure S3 Generating a sample that yields pure hexagonal ice diffraction. First, a $30 \% \mathrm{w} / \mathrm{w}$ polypropylene glycol 425 solution in a $500 \mu \mathrm{~m}$ diameter PET tube was abruptly cooled to $\mathrm{T}=200 \mathrm{~K}$ by unshuttering a cold gas stream. Abrupt cooling to a temperature where the ice nucleation rate was high resulted in an ideal powder pattern with a large width (indicating a small crystallite size) and having a stacking disordered intensity profile. As this sample was slowly warmed, the intensity profile evolved from stacking disordered to purely hexagonal (Kuhs et al., 2012) and the peak breadths decreased, indicating a growth in ice grain size. Even though the solution contains propylene glycol, this component is rejected during ice growth and the ice crystals are comprised of pure water.

Figure S4 (a) The diffraction pattern recorded from the hexagonal ice calibration sample at 250 K , before the loss of ring uniformity. (b) Peak widths in (a), used to estimate the instrumental broadening.

Figure S5 Histogram and fits to the Generalized Extreme Value (GEV) Distribution for (a) $\langle I C S\rangle$ and the Normal Distribution for (b) $\langle D S\rangle$. The fit equation is given above the histograms, and the fit parameters are given in the legend of each histogram.

Table S3 Outlier pixels identified in diffraction images of 60 IRRMC archive data sets. 26 data sets had ice rings visible in diffraction images, and 34 did not have visible ice rings. "Cubic" ice rings are at the positions of the three ice rings expected for pure cubic ice; hexagonal ice and stacking disordered ice also have rings at these positions. "Hexagonal-only ice rings" refers to the ice ring positions not common to hexagonal and cubic ice, but that may be present in stacking disordered ice having a large hexagonal plane fraction.

1: Denotes entries where visual classification differed
2: Denotes entries with resolution less than $3.661 \AA$ making ice undetectable.

Table S5 Confusion matrix for our analysis of the 198 PDB entries in Table S4.
