Abstract. This study uses multi-model ensemble results of 11 models from the 2nd phase of Task
25 Force Hemispheric Transport of Air Pollution (HTAP II) to calculate the global sulfur (S) and
nitrogen (N) deposition in 2010. Modelled wet deposition is evaluated with observation networks
in North America, Europe and Asia. The modelled results agree well with observations, with 76-
83% of stations having predicted within $\pm 50\%$ of observations. The results underestimate SO_4^{2-} ,
 NO_3^- and NH_4^+ wet depositions in some European and East Asian stations, but overestimate
30 NO_3^- wet deposition in Eastern United States. Inter-comparison with previous projects
(PhotoComp, ACCMIP and HTAP I) shows HTAP II has considerably improved the estimation
of deposition at European and East Asian stations. Modelled dry deposition is generally higher
than the “inferential” data calculated by observed concentration and modelled velocity in North
America, but the inferential data has high uncertainty, too. The global S deposition is 84 Tg(S) in
35 2010, with 49% of the deposits on continental regions and 51% on ocean (19% on coastal). The
global N deposition consists of 59 Tg(N) oxidized nitrogen (NO_y) deposition and 64 Tg(N)

reduced nitrogen (NH_x) deposition in 2010. 65% of N is deposited on the continental regions and 35% is on ocean (15% on coastal). The estimated outflow of pollution from land to ocean is about 4 Tg(S) for S deposition and 18 Tg(N) for N deposition. Compared our results to the results in 2001 from HTAP I, we find that the global distributions of S and N depositions have changed considerably during the last 10 years. The global S deposition decreases 2 Tg(S) (3%) from 2001 to 2010, with significant decreases in Europe (5 Tg(S) and 55%), North America (3 Tg(S) and 29%) and Russia (2 Tg(S) and 26%), and increases in South Asia (2 Tg(S) and 42%) and the Middle East (1 Tg(S) and 44%). The global N deposition increases by 7 Tg(N) (6%), mainly contributed by South Asia (5 Tg(N) and 39%), East Asia (4 Tg(N) and 21%) and Southeast Asia (2 Tg(N) and 21%). The NH_x deposition is increased with no control policy on NH_3 emission in North America. On the other hand, NO_y deposition starts to dominate in East Asia (especially China) due to boosted NO_x emission in recent years.

1 Introduction

The nitrogen (N) plays an important role in the balance of the global ecosystem. Human activities such as consumption of fossil fuels, production and usage of N fertilizers and livestock cultivation disturb the N cycle in the ecosystem (Vitousek et al., 1997; Galloway et al., 2008). Estimation under the IPCC SRES A2 scenario shows that the N deposition over land increases by a factor of ~2.5 from 2000 to 2100 (Lamarque et al., 2005). Elevated N deposition can cause exceedance of N critical loads on ecosystems (Sanderson et al., 2006; Sun et al., 2017). 11% of the world's natural vegetation has already received N deposition that exceeds the critical load in 2000 (Dentener et al., 2006). The most affected regions are Eastern Europe (80%), South Asia (60%) and East Asia (40-50%). This percentage will be 40% for the world's protected areas in 2030 (Bleeker et al., 2011). Elevated S and N deposition are also associated with a host of environmental issues such as acidification and eutrophication of the terrestrial system (Bouwman et al., 2002), loss of ecosystem biodiversity (Bobbink et al., 2010), harming the heterotrophic respiration and disturbing the soil decomposition process (Janssens et al., 2010), although some studies found increasing N deposition could benefit the carbon uptake by land processes (Reay et al., 2008; Holland et al., 1997). Similar to the terrestrial system, over-richness of S and N deposition is also a threat to the aquatic system by acidification (Doney et al., 2007) and eutrophication of the ocean (Bergstrom and Jansson, 2006; Jickells, 2006; Jickells et al., 2017).

In order to understand S and N deposition, a number of global scale studies have been conducted in the last decade. Dentener et al. (2006) investigated the current (2000) and future (2030) S and N deposition with multi-model ensemble results of ACCENT IPCC-AR4 experiment (PhotoComp). Model evaluation showed that 60-70% of modelled wet deposition is within $\pm 50\%$ of measurements in Europe and North America. NH_x deposition is overestimated in South Asia and NO_y deposition is underestimated in East Asia. 11% of the world's nature vegetation receives N deposition that exceed the critical load in 2000, and this percentage will increase to 17% under current air quality legislation and 25% under IPCC SRES A2 scenario in 2030. Sanderson et al. (2008) used the ensemble results of the 1st phase of the Task Force Hemispheric Transport of Air Pollution (HTAP I) to estimate the long-range transport of oxidized nitrogen between Europe, North America, South Asia and East Asia. Results showed that 8-15% of NO_x from source regions could be transported beyond the distance of 1000 km, which indicates the impact of inter-continental transport of air pollutants on deposition. Lamarque et al. (2013) calculated the S and N deposition in 2000 using a multi-model ensemble of the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP). Model performance on NO_3^- wet deposition is comparable with PhotoComp and HTAP I, but NH_4^+ wet deposition is not well simulated. Simulations with the projected emissions in 2100 under four Representative Concentration Pathways (RCP) indicated that N deposition is likely to substantially increase in Latin America, Africa and parts of Asia (especially South Asia) in the future. Vet et al. (2014) conducted a comprehensive evaluation on the model performance of HTAP I. The results underestimated the wet deposition at observation sites with highly observed N deposition in North America, Southern and Northern Europe and East Asia. Dry deposition in the Unites States is found to deviate with inferential dry deposition data. Kanakidou et al. (2016) used the ACCMIP simulation results under historical, RCP6.0 and RCP 8.5 emission scenarios to estimate the changes in N deposition driven by human activity in the past (1850), present (2005) and future (2050). Their results showed that organic nitrogen (ON) from primary emission and secondary organic aerosol (SOA) accounted for 20-30% of total N deposition. The impact of human activity on N deposition has increased from 15% in the past to 60% in present years. This impact is likely to persist in the future. Bian et al. (2017) examined the possible factors causing the inter-model diversity in simulating NO_3^- and NH_4^+ deposition by comparing the results of 9 models participating in the 3rd phase of Aerosol Comparisons between Observations

and Models (AeroCom III). The results showed that models have large differences in calculating the pH adjustment for the effective Henry's law constant, which can largely influence the simulation of NH_x wet deposition.

These studies give a clear view to S and N deposition in the early 2000s. However, large changes are seen in the global N emissions in the last decade (van der A et al., 2008), including a large increase in China (Zhang et al., 2009b; van der A et al., 2006; Richter et al., 2005; Kurokawa et al., 2013; Zhang et al., 2007; Li et al., 2017), and general decreases in both Europe (Tørseth et al., 2012) and Eastern United States (Kim et al., 2006). In addition, ground observations and satellite measurements show large increases in the dry deposition in the western United States, Eastern Europe and East China, together with decreases in Eastern United States, Western Europe and Japan (Jia et al., 2016). Thus, a follow-up study is needed to update our knowledge about the S and N deposition with emission changes in the 21st century.

In this study, we use the multi-model mean (MMM) of 11 global models from the 2nd phase of HTAP (HTAP II) project to calculate the S and N deposition in 2010. Section 2 gives a short description of the HTAP II project and introduces the method to develop MMM and metrics for model evaluation. Section 3.1 evaluates MMM performance on wet deposition with observations from networks in North America, Europe and East Asia. The modelled dry deposition is compared with the inferential data in North America (see detail in Section 3.1). We also compare the model performance of this study with previous studies in 2001 of PhotoComp (Dentener et al., 2006), HTAP I (Vet et al., 2014), and ACCMIP (Lamarque et al., 2013). Section 3.2 and Section 3.3 estimate the S and N deposition on continental, coastal and ocean regions in 2010. By comparing our results with deposition in 2001 of HTAP I, we investigate the changes of deposition in the past 10 years. We conclude with the findings in Section 4.

2 Methodology

2.1 Model description and Experiment setup

The HTAP was developed in 2005 aiming at understanding the long-range transport of air pollution and its impact on regional air quality. HTAP I has involved more than 20 global models with base simulation year of 2001. A comprehensive assessment has been published to summarize the findings in HTAP I with respect to the long-range transport of (1) ozone and particulate matter (2) mercury and (3) persistent organic pollutants (HTAP, 2010). The HTAP II

was launched in 2012 with base year of 2010. A prescribed emission inventory called HTAPv2.2 is used by models from different groups to facilitate a fair evaluation of the models' ability and uncertainty (Galmarini et al., 2016). It is a harmonized emission inventory formed by the best estimation of emissions from different organizations, including Environmental Protection Agency (EPA) of United States, the EPA and Environment Canada, the European Monitoring and Evaluation Programme (EMEP) and the Netherlands Organisation for Applied Scientific Research (TNO), the Model Inter-Comparison Study for Asia (MICS-Asia III) and the Emission Database for Global Atmospheric Research (EDGARv4.3). The development of the emission inventory is described in Janssens-Maenhout et al. (2015).

Among the 20 models participating in the HTAP II project (configurations described in Stjern et al. (2016)), 11 models (i.e. CAM-Chem, CHASER_re1, CHASER_t106, EMEP_rv48, GEMMACH, GEOS5, GEOSCHEMAJOINT, OsloCTM3v.2, GOCARTv5, SPRINTARS and C-IFS_v2) submitted the model outputs of S and N deposition. To develop the MMM, all models are interpolated to a uniform $0.1^\circ \times 0.1^\circ$ horizontal resolution (the same resolution as the emission inventory) by linear interpolation. Then the MMM of the emission/deposition quantities of each of S and N is calculated by averaging (arithmetic mean) all available model outputs. More details are demonstrated in Section 2.2. The base year of simulation is 2010, with additional six-month run as model spin-up. The administrative boundaries of 17 regions are shown in Fig. S1. Details about the experiment setup can be found in Galmarini et al. (2016).

2.2 Method for calculating the MMM

To make the discussion clear, we define the terms as follows: The continental regions refer to all land regions including the Antarctic. The coastal regions are defined in Fig. S1. In section 3.2 and 3.3, the S deposition contains gas phase SO_2 deposition and aerosol SO_4^{2-} deposition. The N deposition includes oxidized nitrogen (NO_y) deposition and reduced nitrogen (NH_x) deposition. NO_y deposition is composed of all oxidized nitrogen species except N_2O . Based on the model outputs, NO_y deposition mainly includes NO_2 , HNO_3 , aerosol NO_3^- , peroxyacyl nitrate (PAN) and other organic nitrates than PAN (Orgn). NH_x deposition consists of gas phase NH_3 deposition and aerosol NH_4^+ deposition. Before constructing the MMM, we check the quality of model outputs using two criteria. First, we check the mass balance of each of the models by comparing the global deposition of each with its emission. Models are excluded if their

deposition values fall outside the range of $\pm 20\%$ of their emission values. The second criterion is to check if the result of a model is away from the mean value of all models. We adopt the upper and lower limits as median of models $\pm 1.5 \times$ interquartile by Vet et al. (2014) and check the values separately for all species of deposition and emission. The models used to develop the MMM and their values are summarized in Table S1-S3. After the quality check, we calculate the mean value of each species using equation (1) with all available model outputs. Then, we combine all of the related species into total deposition/emission by equation (2).

$$S_{MMM}(j) = \frac{1}{n} \sum_{i=1}^n S_i(j) \quad (1)$$

$$S_{MMM}(NO_y, NH_x \text{ or } S) = \sum_{j=1}^s S_{MMM}(j) \quad (2)$$

For both equations (1) and (2), i is the individual model and j is the species of deposition/emission from model outputs. $S_i(j)$ is the species j from model i and $S_{MMM}(j)$ is the MMM of species j .

2.3 Model evaluation metrics

To compare the model performance with previous projects consistently, we adopt the following metrics in Lamarque et al., (2013): Linear fit slope, mean bias, mean observation, mean model, correlation coefficient (R) and fraction (of model results) within $\pm 50\%$ (of observations).

In addition, we use 4 statistical metrics following Eq. (3)-(6).

$$\text{NMB (normalized mean bias)} = \frac{\sum_{i=1}^n (M_i - O_i)}{\sum_{i=1}^n O_i} \times 100 \quad (3)$$

$$\text{NME (normalized mean error)} = \frac{\sum_{i=1}^n |M_i - O_i|}{\sum_{i=1}^n O_i} \times 100 \quad (4)$$

$$\text{MFB (mean fractional bias)} = \frac{1}{n} \sum_{i=1}^n \frac{M_i - O_i}{(M_i + O_i)/2} \times 100 \quad (5)$$

$$\text{MFE (mean fractional gross error)} = \frac{1}{n} \sum_{i=1}^n \frac{|M_i - O_i|}{(M_i + O_i)/2} \times 100 \quad (6)$$

For equations (3)-(6), M_i is the model result, O_i is the observation and n is the sample size. NMB, NME, MFB and MFE normalize the model mean bias to avoid data inflation in case of large data range. NMB and NME normalize the mean bias by the observation data and thus may tend toward model overestimation. MFB and MFE normalize the mean bias by the average of observations and model results, considering both model overestimation and underestimation, and thus are less biased. In Section 3.1, we use MFB and MFE as the main metrics to evaluate the model performance.

3 Results

3.1 Evaluation of model performance

3.1.1 Wet deposition

We evaluate the MMM results of SO_4^{2-} , NO_3^- and NH_4^+ wet deposition with site observations in
190 United States, Europe and East Asia. The MMM result is annual deposition in 2010 and the
observation data is 3-year annual average deposition during 2009-2011. The observation data in
United States comes from the National Atmospheric Deposition Program (NADP)
(<http://nadp.sws.uiuc.edu/>). The quality and completeness of the observations are checked
according to the 4 criteria established by the NADP technical committee
195 (<http://nadp.sws.uiuc.edu/documentation/notes-depo.html>). As a result, we use the data from 136
stations of the 267 available stations. The observations in Europe are derived from the European
Monitoring and Evaluation Programme (EMEP) CCC reports
(<http://www.nilu.no/projects/ccc/reports.html>). After checking the data quality and completeness,
we use the data from 82 stations of the 102 available stations. The observations in Asia are from
200 the Acid Deposition Monitoring Network in East Asia (EANET) (<http://www.eanet.asia/>). Data
from 43 stations of the 52 available stations are used for evaluation.

Fig. 1 shows the scatter plots of the MMM SO_4^{2-} , NO_3^- and NH_4^+ wet deposition with
observations at the NADP, EMEP and EANET stations. The SO_4^{2-} wet deposition comprises gas
phase SO_2 and aerosol SO_4^{2-} wet deposition. The NO_3^- wet deposition includes gas phase HNO_3
205 and aerosol NO_3^- wet deposition. The NH_4^+ wet deposition contains gas phase NH_3 and aerosol
 NH_4^+ wet deposition. Performance of individual models can be found in Figs. S2-S4 in the
supplementary material. Fig. 2 displays the spatial distributions of MMM SO_4^{2-} , NO_3^- and NH_4^+
wet deposition (contours) with observations (filled circles). In terms of SO_4^{2-} wet deposition, the
MMM results are consistent with observations at the NADP stations with a close to 1 slope (0.9)
210 and a high R value (0.8) (Fig.1 (a)). The MFB and MFE are 9% and 32%, indicating slight
overestimation. According to Fig. 2(a), the observed SO_4^{2-} wet deposition is highest in
northeastern United States, and this spatial distribution is well captured by MMM. The EMEP
stations are well simulated with low MFB (-7%) and MFE (25%) (Fig. 1(b)). The MMM
predictions are within $\pm 50\%$ of observations at 87% of the stations. According to Fig. 2(b), 1
215 station in Poland and 1 station in Norway, with observed SO_4^{2-} wet deposition of 1000 and 500

mg (S) $\text{m}^{-2} \text{yr}^{-1}$ respectively, are underestimated by 50%. At the EANET stations, very high SO_4^{2-} concentrations were measured at some stations, probably correlated with dust emission (Dentener et al., 2006). Therefore, we ignore the measurements coincident with measured calcium (Ca^{2+}) deposition larger than 20 mole $\text{m}^{-2} \text{yr}^{-1}$. The evaluation (Fig. 1(c)) shows that the

220 SO_4^{2-} wet deposition is generally underestimated at the EANET stations by 23% (MFB) and 44% (MFE). The stations in Korea and Vietnam are generally underestimated by more than 200 mg (S) $\text{m}^{-2} \text{yr}^{-1}$ (Fig. 2(c)). On the other hand, the SO_4^{2-} wet deposition is generally well simulated in Indonesia, Philippines, Thailand and Japan. Overall, 76% of the stations predicted quantities within $\pm 50\%$ of observations. The EANET stations have the highest model bias among the 3

225 networks. It should be noted that for the 3 excluded stations (located in China) with high Ca^{2+} deposition, the SO_4^{2-} wet deposition is largely underestimated by more than 1000 mg (S) $\text{m}^{-2} \text{yr}^{-1}$ (not shown in figures). If we include these stations in the model evaluation, the mean bias for East Asia increases from 160 mg (S) $\text{m}^{-2} \text{yr}^{-1}$ to 300 mg (S) $\text{m}^{-2} \text{yr}^{-1}$. We also realize that the observation stations in China are mainly located along the eastern and southern coast, while the

230 highest deposition is found in the inland areas. Therefore, it is hard to conduct a comprehensive evaluation over this region.

For NO_3^- wet deposition, the MMM results agree well with observations at the NADP stations, as shown by the linear regression line in Fig. 1(d) with slope of 1.2 and R value of 0.9. However, the amount of deposition is overestimated by 33% (MFB) and 36% (MFE). According

235 to Fig. 2(d), the over-predicted stations are mainly located in Midwestern and Southeast United States. At the EMEP stations, the NO_3^- wet deposition is well simulated with low MFB of -5% and MFE of 24% (Fig. 1(e)). The modelled deposition is within $\pm 50\%$ of observed deposition at more than 90% of the stations. The MMM results are close to the observations at stations with deposition lower than 400 mg (N) $\text{m}^{-2} \text{yr}^{-1}$, but generally underestimate the deposition at stations

240 with higher observations. According to Fig. 2(e), 3 stations in Poland, Norway and Spain underestimate wet deposition by 430 (59%), 420 (63%) and 290 (67%) mg N $\text{m}^{-2} \text{yr}^{-1}$, respectively. Besides, the stations in Germany generally under-predict these values by 100-200 mg (N) $\text{m}^{-2} \text{yr}^{-1}$. The NO_3^- wet deposition at the EANET stations is well simulated with MFB (-3%) and MFE (43%) (Fig. 1(f)). The model estimations are within $\pm 50\%$ of observations for

245 77% of the stations. According to Fig. 2(f), 1 station in Central China is overestimated by 400 (130%) mg (N) $\text{m}^{-2} \text{yr}^{-1}$. On the contrary, 3 stations in Thailand, Vietnam and Malaysia are

underestimated by 570 (78%), 350 (66%) and 200 (64%) mg (N) m⁻² yr⁻¹. Overall, 83% of the
MMM results are within ±50% of observations. The NADP stations have the highest MFB due to
a generally positive bias in the eastern United States. The EANET stations have the highest MFE
250 value, mainly due to the underestimation in Southeast Asia.

The modelled NH₄⁺ wet deposition agrees well with observations at the NADP stations
with MFB of 7% and MFE of 25% (Fig. 1(g)). 88% of modelled deposition is within ±50% of
observations as shown by the R value of 0.9. The MMM has well captured the high deposition in
the United States Midwest, but slightly underestimates the deposition in the Southeast (Fig.
255 2(g)). At the EMEP stations, the NH₄⁺ wet deposition is well simulated with MFB of -1% and
MFE of 36% (Fig. 1(h)). The MMM results are close to the observations at most stations and
well reproduce the high deposition in Germany and Italy (Fig. 2(h)). Some stations in Norway
and Poland are slightly underestimated by 100-200 mg (N) m⁻² yr⁻¹. These stations all report
observations of higher deposition than 500 mg (N) m⁻² yr⁻¹. The NH₄⁺ wet deposition is
260 underestimated at the EANET stations by 10% (MFB) and 50% (MFE) (Fig. 1(i)). The MMM
has well captured the high deposition in Eastern China and Indonesia, but generally
underestimates the NH₄⁺ wet deposition at the Russian stations (Fig. 2(i)). In addition, the
observed deposition at the 3 Korean stations is relatively high (~500-600 mg (N) m⁻² yr⁻¹), but
the MMM fails to reproduce any of them. There could be a missing emission source in that
265 region. Overall, 81% of the MMM predictions are within ±50% of observations. The NH₄⁺ wet
deposition is somewhat underestimated in all 3 regions, especially in East Asia.

Table 1 compares the model performance of this study (HTAP II) with previous projects
of PhotoComp (Dentener et al., 2006), HTAP I (Vet et al., 2014) and ACCMIP (Lamarque et al.,
2013). It should be noted that the emission inputs, simulation periods and participating groups of
270 this study (year 2010) are different from those of the previous projects (year 2001). Although the
observations are from the same networks, the previous projects used 3-year averaged
observations of 2000-2002 and this study used those of 2009-2011. Due to these differences, the
model performances may not be totally comparable. In terms of SO₄²⁻ wet deposition, the model
performance is similar to that for previous projects in North America, with 4-6% higher
275 percentage of stations within ±50% of observations. Large improvement is found in Europe. The
absolute mean bias decreases from 50-130 mg (S) m⁻² yr⁻¹ to 30 mg (S) m⁻² yr⁻¹. There is 10%
increase in the fraction of stations within ±50% of observations. At the East Asian stations, the

absolute mean bias decreases slightly from 180–290 mg (S) m⁻² yr⁻¹ to 160 mg (S) m⁻² yr⁻¹. But the R value and fraction within ±50% have somewhat declined. For NO₃⁻ wet deposition, HTAP II performs similar to the ensembles used in previous projects in North America, but slightly better in Europe with lower mean bias and 5% increase in the fraction within ±50% of observations. The model mean bias at the Asian stations has decreased significantly from ~50 mg (N) m⁻² yr⁻¹ to ~1 mg (N) m⁻² yr⁻¹. However, the biases for individual models are large (Fig. S3). Large negative model bias is found in Southeast Asia and improvements are needed in the future. In terms of NH₄⁺ wet deposition, HTAP II shows similar R values to those of ensembles used for the previous projects at the NADP stations, with slightly lower model bias. However, HTAP II shows considerable improvement in Europe. The slope of the regression line increases from 0.3–0.4 to 0.6 and the mean bias decreases from as large as -95 mg (N) m⁻² yr⁻¹ to -4 mg (N) m⁻² yr⁻¹. For Asia, the slope, mean bias and R values for HTAP II are all within the ranges of the previous projects, while the absolute mean bias decreases from 70–140 mg (N) m⁻² yr⁻¹ to 30 mg (N) m⁻² yr⁻¹.

3.1.2 Dry deposition

The number of dry deposition measurements is limited due to difficulty in measuring the dry deposition directly by instruments. This study evaluates the dry deposition in United States using information from the Clean Air Status and Trends Network (CASTNET). Instead of direct measurements, the data are produced by an “inferential” method, using calculations of the measured concentration of species and modelled dry deposition velocities. The uncertainty is estimated to be 10–20% in the measurement of mixing ratio of species, 20% in the calculated velocity and ~20% when lacking of hourly concentration for species with strong diurnal variation (Zhang et al., 2009a). Schwede et al. (2011) compared the CASTNET data with the Canadian Air and Precipitation Monitoring Network (CAPMoN). The CASTNET data is 54% lower for SO₂ dry deposition and 47% lower for HNO₃ dry deposition than CAPMoN, mainly due to using different models to calculate the dry velocity.

We use the 3-year average data of 2009–2011 from CASTNET and adopt the same selection criteria as we did for the wet deposition measurements. Data from 81 stations out of 85 available stations is used for comparison. Fig. 3 shows the scatter plots of the MMM SO₂, SO₄²⁻, NO₃⁻, HNO₃ and NH₄⁺ dry deposition with inferential data at the CASTNET stations.

Performances of individual models can be found in Fig. S5-S9 in the supplementary material. The modelled SO₂ dry deposition is 240 (170%) mg (S) m⁻² yr⁻¹ higher than the inferential data and only 5% of the stations is within ±50% of the inferential values. There are smaller discrepancies for values of SO₄²⁻ dry deposition (14 mg (S) m⁻² yr⁻¹ and 60%) between model and inferential results. Modelled NO₃⁻, HNO₃ and NH₄⁺ dry deposition is generally 0.5-1 times higher than the inferential data and the fraction within ±50% is about 15%. Fig. 4 shows the spatial distributions of MMM dry deposition (contours) with the inferential data (filled circles). The MMM results are consistent with the inferential data in the western United States, where the dry deposition is generally low. And both datasets predict high NO₃⁻ dry deposition in western California. Large disagreements are found in the eastern United States. In the Midwest (mainly Indiana and Ohio states), although both results estimate higher N (NO₃⁻, HNO₃ and NH₄⁺) dry deposition in this region than the others, the prediction of MMM is 20-30 mg (N) m⁻² yr⁻¹ higher than the inferential data at every station. In addition, the MMM estimates much higher deposition in southern and northeastern United States than in the western United States, but this pattern is not clear from the inferential data.

Table 2 compares the model performance of this study (HTAP II) with that of the models used in the previous projects of HTAP I (Vet et al., 2014) and ACCMIP (Sun et al., 2017). HTAP I used the 2001 simulation results and compared them with 3-year average (2000-2002) CASTNET data. ACCMIP used 10-yr averages of both MMM and CASTNET data from 2000 to 2009. The N dry deposition values for all projects contain NO₃⁻, NH₄⁺ and HNO₃ and the S dry deposition includes SO₂ and SO₄²⁻. Both HTAP I and HTAP II overestimated the S and N dry deposition, but HTAP II has ~100 mg(S) m⁻² yr⁻¹ and ~80 mg(N) m⁻² yr⁻¹ lower mean bias than HTAP I. The comparison with ACCMIP results may not be solid since there are large differences in simulation periods. Generally, the HTAP II performance is similar to ACCMIP for NH₄⁺, SO₂ and SO₄²⁻ dry deposition simulation, but has larger mean bias for HNO₃ dry deposition prediction.

3.2 S deposition

Table 3 lists the calculated amount of S emission and deposition on continents, coastal regions and oceans. Fig. 5 presents the distribution of S emission and deposition from MMM results. The distributions of components of S deposition are shown in Fig. S10 in the

supplementary material. The global S deposition is 84 Tg(S) in 2010, with 49% deposits on non-coastal continents, 32% deposits on non-coastal ocean and 19% deposits on coastal area. For continental non-coastal regions, East Asia receives the largest amount of S deposition (17%). The highest S deposition is found in Eastern China ($2000 \text{ mg(S) m}^{-2} \text{ yr}^{-1}$) (Fig. 5(b)). Other regions with largely extended areas of high S deposition are the Indian peninsula ($800\text{--}1200 \text{ mg(S) m}^{-2} \text{ yr}^{-1}$), Malaysia and Indonesia ($\sim 1200 \text{ mg(S) m}^{-2} \text{ yr}^{-1}$), United States Midwest ($800\text{--}2000 \text{ mg(S) m}^{-2} \text{ yr}^{-1}$), Mexico and Central America ($400\text{--}800 \text{ mg(S) m}^{-2} \text{ yr}^{-1}$), Peru and Chile ($400\text{--}600 \text{ mg(S) m}^{-2} \text{ yr}^{-1}$), Eastern Europe ($\sim 800 \text{ mg(S) m}^{-2} \text{ yr}^{-1}$) and the northeastern Middle East ($500\text{--}1200 \text{ mg(S) m}^{-2} \text{ yr}^{-1}$). The distribution of high deposition regions agrees very well with high S emission regions (Fig. 5(a)). For coastal regions, East Asia and Southeast Asia receive the most S deposition (3% and 3% respectively). The east coast of East Asia and North America and all of the coast of India have relatively high deposition ($400\text{--}800 \text{ mg(S) m}^{-2} \text{ yr}^{-1}$), followed by the west coast of Mexico ($\sim 400 \text{ mg(S) m}^{-2} \text{ yr}^{-1}$). The ocean serves as an important sink of S deposition. This study estimates 43 Tg(S) of S deposition on the ocean in 2010 (include non-coastal and coastal), and accounts for 51% of global S deposition. The ratio is similar to the 51% estimated by Dentener et al. (2006) and 46% estimated by Vet et al. (2014) in 2001.

We calculate the ratio of S deposition to S emission (Fig. 5(c)). Because it is not clear how dimethyl sulphide (DMS) emission will transfer to S deposition, this ratio does not represent the transformation of S emission to deposition. For continental non-coastal regions, the average ratio is 85% (86% if taking consideration of coastal regions). In high emission regions, this ratio can be viewed as the “scavenging” effect of S pollution by deposition. In major source regions of S emission (i.e. North China Plain, Midwest of United States and India), the ratios are only slightly higher than 50%, while in low S emission regions ($<10 \text{ mg(S) m}^{-2} \text{ yr}^{-1}$), the ratios could exceed 400 % (areas with white color in Fig. 5(c)). This result indicates that the deposition in these regions is largely affected by long-range transport of pollution from other regions. The impact of intercontinental transport of air pollutants on deposition can be quantified by the emission perturbation experiments in HATP II. Results from those experiments will be discussed in another paper.

We compare the S emission and deposition in 2010 from HTAP II with that in 2001 from HTAP I (Vet et al., 2014) (Table 3). We re-calculate the HTAP I results according to the regions defined in HTAP II (Fig. S1), so the HTAP I results may look different from those in Table 2 of

Vet et al. (2014). Because different models were used for each of the two ensembles compared, associated uncertainty is expected. In addition, emissions in HTAP I were not prescribed, so each modelling group used its own best estimation of emissions (Sanderson et al., 2008). Conversely, all models in HTAP II, used the same anthropogenic emission values (although there were still differences in natural emission). Globally, the S emission decreases by 5 Tg(S) from 2001 to 2010, with 8 Tg(S) (13%) decrease in continental non-coastal regions, 6 Tg(S) (32%) increase in non-coastal ocean regions and 3 Tg(S) (15%) decrease in coastal regions. For continental non-coastal regions, there are big drops in S emissions from Europe (6 Tg(S) and 61%), North America (3 Tg(S) and 34%) and Russia (2 Tg(S) and 44%). On the other hand, South Asia and Middle East have 2 Tg(S) (56%) and 1 Tg(S) (69%) increase in S emissions. East Asia, one of the main contributors to S emission seems to show little change between 2001 and 2010. However, it has experienced large changes during these 10 years, with stable annual increases from 2000 to 2005 due to increased energy consumption and decreases after 2006 owing to the successful implementation of the SO₂ control policies in China's 11th Five-Year-Plan (FYP) (Lu et al., 2010). For coastal regions, Europe has experienced a 2 Tg(S) (54%) decrease and East Asia has experienced a 1 Tg(S) (43%) decrease in S emission. Other regions have relatively small (0-0.6 Tg(S)) changes. The global S deposition decreases by 2 Tg(S), with 5 Tg(S) (11%) decrease in continental non-coastal regions, 4 Tg(S) (16%) increase in non-coastal ocean regions and 1 Tg(S) (5%) decrease in coastal regions. The regions with the largest change in deposition coincide with those having big changes in emission. For instance, Europe experiences 5 Tg(S) decrease in S deposition with 8 Tg(S) decrease in emission, and South Asia receives 2 Tg(S) more S deposition with 2 Tg(S) increase in emission. Fig. S11(b) compares the S deposition in HTAP II with that in HTAP I. Declined S deposition is found in large areas of the eastern United States and Europe (400-1,500 mg(S) m⁻² yr⁻¹). Regions with increased S deposition are India and Indonesia (100-800 mg(S) m⁻² yr⁻¹). In China, there is a mixture of both increases and decreases in S deposition over different areas. The changes in S depositions agree well with changes in S emissions (Fig. S11(a)). During China's 11th FYP, one of the main technologies to control the SO₂ emission was to install the Flue Gas Desulfurization (FGD) on power plants (Cao et al., 2009). The effectiveness of this technology in removing SO₂ emission varies considerably regionally, as a result of several factors such as the coverage of FGD technology on power plants, local reduction targets and stringency of policy implementation by local governments. On the

400 other hand, new sources of SO₂ emission, such as newly built power plants, are found responsible for the increased S emissions and deposition over some areas in China (Tan et al., 2017).

3.3 N deposition

3.3.1 NO_y deposition

405 Table 4 summarizes the NO_y emission and deposition in each region and Fig. 6 presents the distribution from MMM results. Distributions of components of NO_y deposition are shown in Fig. S12 in the supplementary material. The global NO_y deposition is 59 Tg(N) in 2010, with 62% of deposits on non-coastal continents, 22% of deposits on non-coastal ocean and 16% of deposits on coastal areas. For continental non-coastal regions, East Asia receives the largest NO_y deposition (14%). The highest NO_y deposition is found in northeastern China (2000 mg(N) m⁻² yr⁻¹), followed by the Indian peninsula (800-1200 mg(N) m⁻² yr⁻¹), Malaysia and Indonesia (500-800 mg(N) m⁻² yr⁻¹), Germany, Switzerland and Poland (500-600 mg(N) m⁻² yr⁻¹), northern Sub-Saharan Africa (300-500 mg(N) m⁻² yr⁻¹), northeastern Middle East (400-500 mg(N) m⁻² yr⁻¹), United States Midwest (500-600 mg(N) m⁻² yr⁻¹) and Brazil (300-600 mg(N) m⁻² yr⁻¹).

415 For coastal regions, the east coast of East Asia also receives the largest amount of NO_y deposition (600 mg(N) m⁻² yr⁻¹ and 4%). Relatively high deposition is found on the east coast of North America (150-400 mg(N) m⁻² yr⁻¹), all of the coast of India (300-500 mg(N) m⁻² yr⁻¹), the west coast of Europe and all of the coast of Southeast Asia (150-200 mg(N) m⁻² yr⁻¹). This study estimates 23 Tg(N) of NO_y deposition on the ocean in 2010 (include ocean non-coastal and coastal), similar to Dentener et al. (2006)'s estimation of 23 Tg(N), Duce et al. (2008)'s estimation of 14-32 Tg(N) and Vet et al. (2014)'s estimation of 20 Tg(N). About 38% of global NO_y deposits on the ocean, lower than 43% in PhotoComp (Dentener et al., 2006) and 42% in HTAP I (Vet et al., 2014), but higher than 30% estimated by Lamarque et al. (2005). It should be noted that these values partly depend on the land-ocean mask, which may differ among different studies. For non-coastal ocean regions, the NO_y deposition is 13 Tg(N), accounts for 22% of the global deposition. While the emission from oceans is only 2 Tg(N), about 4% of global emission. The difference of 11 Tg(N) indicates NO_y transport from continents to the open ocean. Antarctic have near zero NO_x emission, but receive 0.1 Tg(N) NO_y deposition. Deposition has been a non-negligible pathway that human pollution is contaminating the nearly untouched areas.

425

430 We calculate the ratio of NO_y deposition to NO_x emission (Fig. 6(c)). In continental non-
coastal regions, the average ratio is 74% (81% if taking consideration of coastal regions). In high
 NO_x emission regions (i.e. North America, East Asia and South Asia), an average 60-80% of the
 NO_y is removed by deposition, with large regional variation. For low emission regions (i.e. North
Africa and Central Asia), the ratio can reach higher than 90%. Also in coastal regions and open
435 ocean, the ratio is generally over 200%. Instead of the local emission, the transport of air
pollutants from elsewhere is the major source of deposition.

3.3.2 NH_x Deposition

The global NH_x deposition is 54 Tg(N) in 2010, with 69% of deposits on continental non-coastal
regions, 19% of deposits on ocean non-coastal regions and 13% of deposits on coastal regions
440 (Table 4). For continental non-coastal regions, South Asia receives 16% of global NH_x
depositions, followed by East Asia (13%). The whole Indian peninsula receives higher NH_x
depositions than $2,000 \text{ mg(N) m}^{-2} \text{ yr}^{-1}$ (Fig. 6(e)). Also, the Asian regions have several high
deposition areas: the North China Plain and Indonesia ($1,200\text{-}2,000 \text{ mg(N) m}^{-2} \text{ yr}^{-1}$), Japan,
Thailand, Vietnam and Myanmar ($500\text{-}600 \text{ mg(N) m}^{-2} \text{ yr}^{-1}$). Other regions with high NH_x
445 deposition are: the United States Midwest, Germany, France, Northern Italy, Southern Brazil
and Ethiopia ($400\text{-}800 \text{ mg(N) m}^{-2} \text{ yr}^{-1}$). Distributions of components of NH_x deposition are
shown in Fig. S13 in the supplementary material.

Coastal regions of Southeast Asia (3%), East Asia (2%) and South Asia (2%) receive the
largest NH_x deposition ($\sim 200\text{-}400 \text{ mg(N) m}^{-2} \text{ yr}^{-1}$). The east coast of North America and Mexico
450 also have high NH_x deposition ($150\text{-}200 \text{ mg(N) m}^{-2} \text{ yr}^{-1}$). Compared to NO_y deposition, the NH_x
deposition on coastal regions is relatively lower. The ocean receives 17 Tg(N) of NH_x deposition
in 2010, within the range of 13-29 Tg(N) estimated by Duce et al. (2008), but lower than 23.5
Tg(N) estimated by Dentener et al. (2006) and 21.4 Tg(N) estimated by Vet et al. (2014). 31% of
 NH_3 emission is deposited on ocean areas, similar to 31% estimated by Dentener et al. (2006)
455 and 30% estimated by Lamarque et al. (2005), but slightly lower than 37% in PhotoComp
(Dentener et al., 2006) and 37% in HTAP I (Vet et al., 2014). The ocean emitted 12 Tg(N) of
 NH_3 in 2010, which means that at least 5 Tg(N) of NH_x deposition on oceans in 2010 came from
continental regions. This value is considerably lower than the 13 Tg(N) of deposition-emission
difference for NO_y (including the 2 Tg(N) difference on coastal regions). A possible explanation

460 is that NH_3 has a short lifetime in the atmosphere, which makes it more likely to deposit close to where it is emitted (Shen et al., 2016), while NO_x can be oxidized to organic nitrate (Moxim et al., 1996), which facilitates the long-range transport from land to open ocean.

We calculate the ratio of NH_x deposition to NH_3 emission (Fig. 6(f)). The average ratio is 87% for continental non-coastal regions (92% if also considers the coastal regions). The ratios
465 are generally higher than those of NO_y deposition (74% and 81%), since large a proportion of NH_x deposits near the source. The ratios are generally over 400% for coastal areas, but less than 100% on open ocean (70-90%). This is because there is less continental NH_x transported to the open ocean than to coastal regions.

3.3.3 N deposition

470 The global N deposition in 2010 is 113 Tg(N), with 65% of deposits on the continental non-coastal regions, 20% on non-coastal oceans and 15% on coastal regions (Table 4). East Asia (13%) and South Asia (11%) receive the largest amount of N deposition, consistent with the fact that they are also the largest N emission sources (16% and 13% respectively). The deposition reaches 3000 mg(N) m^{-2} yr^{-1} over Eastern China (especially North China Plain) and 2000 mg(N)
475 m^{-2} yr^{-1} over India and Southeast Asia (Thailand, Vietnam and Malaysia). Other regions of high N deposition are the United States, northeast Western Europe (800-1200 mg(N) m^{-2} yr^{-1}), Mexico, Central America, Brazil, northern Sub-Saharan Africa and the northeastern Middle East (500-600 mg(N) m^{-2} yr^{-1}). For coastal regions, the east coast of the United States, all coasts of India and the east coast of East Asia are identified with relatively high deposition (>600 mg(N)
480 m^{-2} yr^{-1}).

Table 5 compares the N emission and deposition in HTAP II with HTAP I. The global N emission increases from 105 Tg(N) to 115 Tg(N), with a 12 Tg(N) (15%) increase in continental non-coastal regions and a 2 Tg(N) (14%) decrease in coastal regions. The change on the ocean is small due to increased NO_y deposition but decreased NH_x deposition. For continental non-coastal
485 regions, positive changes happen in South Asia (5 Tg(N), 56%), East Asia (4 Tg(N), 26%) and Southeast Asia (2 Tg(N), 58%), while the emission in Europe decreases by 1 Tg(N) (12%). The emission changes in coastal regions are relatively small. The global N deposition increases by 7 Tg(N), with a 9 Tg(N) (14%) increase in continental non-coastal regions and a 2 Tg(N) decrease in ocean regions. Asian regions also have experienced the largest increases in deposition, and the

490 amounts are identical with corresponding emission changes. Fig. S14 (b) compares the
distribution of N deposition in HTAP II with HTAP I. Elevated N deposition is found in India,
Indonesia and North China Plain ($1,500 \text{ mg(N) m}^{-2} \text{ yr}^{-1}$). Regions with small increases are Japan,
the northern Middle East, northwestern Brazil and Mexico ($\sim 200 \text{ mg(N) m}^{-2} \text{ yr}^{-1}$). On the other
hand, the N deposition in the eastern United States and Europe have decreased by 200-400
495 $\text{mg(N) m}^{-2} \text{ yr}^{-1}$.

The global N dry and wet deposition is 40 Tg(N) yr^{-1} and 73 Tg(N) yr^{-1} in 2010,
respectively. We calculate the ratio of dry deposition as

$$\frac{\text{dry deposition}}{\text{dry deposition} + \text{wet deposition}} \times 100\%.$$

500

For continental non-coastal regions, about 44% (range from 35-61%) of the N deposition comes
from dry deposition (42% if take coastal regions into consideration). If the overestimation of N
dry deposition in Section 3.1.2 is considered, this ratio could be even lower. Desert areas (e.g.,
the Sonoran, Mojave and Chihuahuan deserts near the west coast of North America, the Sahara
505 Desert in North Africa, the Arabian Desert in Middle East and the Great Victoria Desert in
Australia) are seen with high ratios of dry deposition (80%) (Red color regions in Fig. 7(c)). This
outcome is reasonable since these areas generally lack precipitation. Low fractions of dry
deposition (30%) are found in Russia, Western China, Southeast Asia, Australia and Central
America. Almost all coastal regions are dominated by wet deposition. A study by Jickells (2006)
510 reported a dry deposition ratio of 21-45% for the east coast of the United States and a study by
Baker et al. (2010) suggested a ratio of 15-22% for the Atlantic Ocean. Our study receives
similar ratios for these coastal regions. A study by Bey et al. (2001) found an outflow of NO_y
from Asia over the Western Pacific Ocean through deposition. According to this study, about
70% of this land-to-ocean export of NO_y deposition is through wet deposition (Fig. 7 (a)).

515 The NH_x and NO_y deposition is 54 Tg(N) yr^{-1} and 59 Tg(N) yr^{-1} in 2010, respectively.
The average ratio of NH_x deposition (calculated as $\frac{\text{NH}_x \text{ deposition}}{\text{NH}_x \text{ deposition} + \text{NO}_y \text{ deposition}} \times 100\%$) for
continental non-coastal regions is 47% (45% if coastal regions are taken into consideration).
South Asia (71%) and Southeast Asia (63%) are dominated by NH_x deposition, owing to high
local NH_3 emission, while the Middle East (25%) and North Africa (34%) are dominated by NO_y

520 deposition. Fig. 7(f) shows the global distribution of the ratio of NH_x deposition. Except the high ratio found in the Indian peninsula, Southeast Asia, Southeast Brazil, South Argentina and New Zealand (70-80%) and Eastern Asia (~60%), other continental non-coastal regions are mainly dominated by NO_y deposition. This is consistent with finding by ACCMIP (Sun et al., 2016). We compare the ratio of NH_x deposition in 2010 (HTAP II) with that in 2001 (HTAP I) (Fig. S15).
525 In United States, the ratio of NH_x deposition in California was 15-20% in 2001 and increases to 40-60% in 2010. The ratio in Alaska also increases from 30-40% to 50%. There is a generally 5-10% increase over the eastern United States. This is consistent with an observed large increase of the NH_x depositions and decrease of NO_y depositions in northeastern United States from 1990s to 2010s (Du et al., 2014; Li et al., 2016). A possible explanation is that the implementation of
530 emission control strategies such as the Clean Air Act (CAA) has resulted in a large reduction in NO_x emissions, which lowered the NO_y deposition in the United States (Lloret and Valiela, 2016). This benefit is compensated by increasing NH_x deposition because no limitation is implemented on NH_3 emission (Kanakidou et al., 2016; Li et al., 2016). Some regions have small increases in the ratio of NH_x deposition, such as North Europe (Norway) (5%), Southeast Asia (10%) and
535 Western Australia (10%). On the other hand, a 30% decrease is found in southeastern China, mainly due to the large increase in NO_x emission during the last decade.

4 Conclusions

We calculate the S and N deposition in 2010 using the multi-model mean (MMM) of an 11-model ensemble from the HTAP II project. The model performance on wet deposition is
540 evaluated with measurement networks of NADP over North America, EMEP over Europe and EANET over East Asia. The modelled wet deposition compares favorably with the observations. About 76-83% of stations are predicted within $\pm 50\%$ of observations. SO_4^{2-} wet deposition is underestimated in East Asia by 20%, especially at 3 Chinese stations with high Ca^{2+} concentration. Because the locations of the Chinese stations don't cover the areas with highest
545 deposition, it is hard to provide a comprehensive evaluation over this region. For NO_3^- wet deposition, 20% positive model bias is generally found at stations in eastern United States, while some European (Poland, Norway and Spain) and East Asian (in Southeast Asia) stations with high observed deposition are underestimated by about 60-70%. NH_4^+ wet deposition is underestimated in Europe (especially in Norway and Poland) and East Asia (especially in Russia

550 and Korea). An inter-comparison is conducted with previous projects of PhotoComp, ACCMIP
and HTAP I. HTAP II has significantly improved the estimation of both S and N deposition at
European stations compared to that in previous projects. Improved estimates are also found in
East Asia. Modelled dry deposition is compared with the inferential data from CASTNET in
North America. The MMM results are generally higher than the inferential data by 50-170%,
555 which is also reported in ACCMIP and HTAP I studies.

We calculate the S and N depositions on lands, costal zones and open oceans. The global
S deposition is 84 Tg(S) in 2010, with 49% deposits on continental non-coastal regions, 32%
deposits on non-coastal oceans and 19% deposits on coastal regions. The global N deposition is
113 Tg(N) in 2010, of which 59 Tg(N) is NO_y deposition and 64 Tg(N) is NH_x deposition. 65%
560 of N is deposited on the continental non-coastal regions and 35% is on oceans (including 15% on
coastal regions). For continental regions, high S deposition is found in Asia regions (East Asia,
South Asia and Southeast Asia), United States Midwest, Central America and Eastern Europe.
For N deposition, high deposition is also identified in the above-mentioned regions plus the Sub
Sahara Africa and Brazil. For coastal regions, the east coast of Asia, all coasts of India and
565 Malaysia and east coast of Unites States are seen with relatively high S and N deposition.
According to our estimation, about 4 Tg(S) of S deposition and 18 Tg(N) of N deposition are
exported from land to ocean, including 0.3 Tg(S) and 4 Tg(N) in coastal regions.

We compare the HTAP II results in 2010 with HTAP I in 2001 by using the same land-
ocean mask. The S deposition decreases 2 Tg(S) from 2001 to 2010, with significant decreases in
570 Europe (5 Tg(S)), North America (3 Tg(S)) and Russia (2 Tg(S)), and increases in South Asia (2
Tg(S)) and the Middle East (1 Tg(S)). East Asia doesn't have large changes in its S deposition
due to increased S emission from 2001-2005 and a continuous reduction in S emission starting
from 2006 owing to the SO₂ control policies in China's 11th FYP. The N deposition increases by
7 Tg(N). The increased N emissions from South Asia (5 Tg(N)), East Asia (4 Tg(N)) and
575 Southeast Asia (2 Tg(N)) lead to identical amounts of elevation in deposition in corresponding
regions. We also compare the ratio of NH_x deposition in total N deposition between HTAP I and
HTAP II. The ratio has increased in some regions of North America, especially in California
(~20%), Alaska (~10%) and the eastern United States (5-10%), which agrees well with recent
observational and modelling studies in United States. A small increase in the ratio of NH_x
580 deposition is found in North Europe (Norway) (5%), Southeast Asia (10%) and Western

Australia (10%). On the other hand, NO_y deposition starts to dominate in East Asia (especially China) due to increased NO_x emission in recent years.

This study updates our knowledge about the global S and N deposition in 2010. We find that the global distributions of S and N depositions have changed considerably during the last 10
585 years, with decreases in North America and Europe and increases in Asian regions. Further studies could determine how much these changes could affect the source-receptor relationship on deposition between continents and the impact of this relationship on global agriculture and ecosystems?

Acknowledgements

590 We thank all participating modelling groups in HTAP II for providing the simulation data. We thank Dr. Robert Vet for providing the multi-model ensemble results of HTAP I. The National Center for Atmospheric Research is sponsored by the National Science Foundation.

775 Fig. 1 Evaluation of MMM performance of SO_4^{2-} , NO_3^- and NH_4^+ wet deposition ($\text{mg (N or S) m}^{-2} \text{ yr}^{-1}$) at NADP (left), EMEP (middle) and EANET (right) stations. The MMM is the annual wet deposition in 2010 and the observation is 3-year average annual data of 2009-2011. Performances of individual models are in Fig. S2-S4 in the supplementary material.

780 Fig. 2. Distribution of SO_4^{2-} , NO_3^- and NH_4^+ wet deposition ($\text{mg (N or S) m}^{-2} \text{ yr}^{-1}$) of MMM and observation. The MMM is the annual wet deposition in 2010 and the observation is 3-year average annual data of 2009-2011. Contours are MMM results and filled circles are observation.

785 Fig. 3 Evaluation of MMM performance of SO_2 , SO_4^{2-} , NO_3^- , HNO_3 and NH_4^+ dry deposition ($\text{mg (N or S) m}^{-2} \text{ yr}^{-1}$) at CASTNET stations. The MMM is the annual dry deposition in 2010 and the observation data is 3-year average annual data during 2009-2011 from CASTNET network. Performances of individual models are in Fig. S5-S9 in the supplementary material.

790 Fig. 4. Distribution of SO_2 , SO_4^{2-} , NO_3^- , HNO_3 and NH_4^+ dry deposition ($\text{mg (N or S) m}^{-2} \text{ yr}^{-1}$) of MMM and observation. The MMM is the annual dry deposition in 2010 and the observation is 3-year average annual data of 2009-2011. Contours are MMM results and filled circles are inferential data from CASTNET.

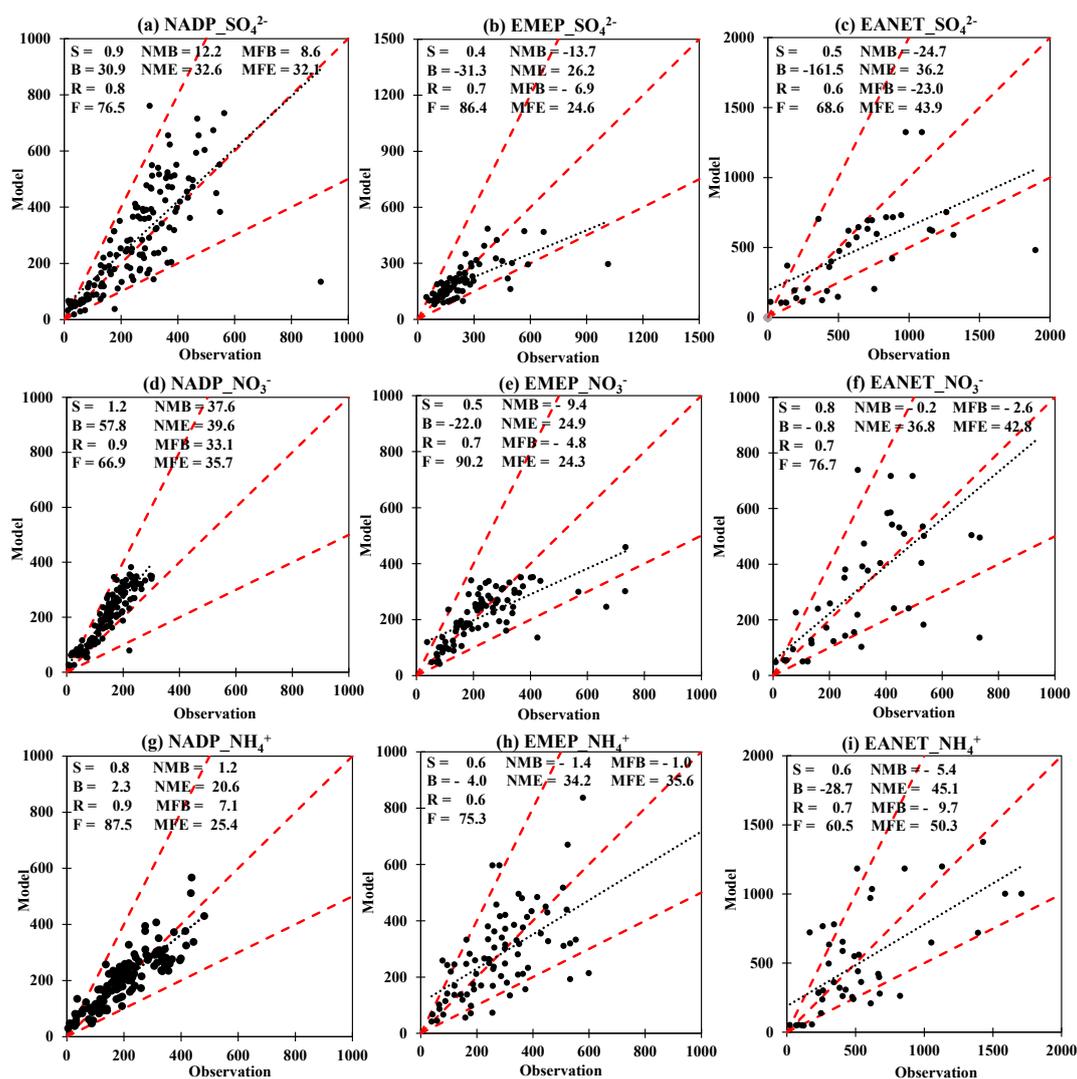

795 Fig. 5 (top panel) MMM results of S emission and deposition in 2010 ($\text{mg(S) m}^{-2} \text{ yr}^{-1}$) and ratio of S deposition in S emission (%). (bottom panel) MMM results of S dry and wet deposition in 2010 ($\text{mg(S) m}^{-2} \text{ yr}^{-1}$) and ratio of dry deposition in total (wet+dry) deposition (%).

800 Fig. 6 MMM results of NO_x , NH_3 and $\text{N}(\text{NO}_x + \text{NH}_3)$ emission ($\text{mg(N) m}^{-2} \text{ yr}^{-1}$) (left panel), NO_y , NH_x and $\text{N}(\text{NO}_y + \text{NH}_x)$ deposition ($\text{mg(N) m}^{-2} \text{ yr}^{-1}$) in 2010. (middle panel), ratio of NO_y , NH_x and N deposition to NO_x , NH_3 and $\text{N}(\text{NO}_x + \text{NH}_3)$ emission (%) (right panel). purple colors represent regions where deposition is larger than emission.

805 Fig. 7 (top panel) The percentage of dry deposition in wet+dry deposition for NO_y , NH_x and $\text{N}(\text{NO}_y + \text{NH}_x)$ deposition. The ratio is calculated as $(\text{dry deposition}) / (\text{dry} + \text{wet deposition}) \times 100\%$. (bottom panel) The percentage of NH_x deposition in $\text{N}(\text{NO}_y + \text{NH}_x)$ deposition for wet, dry and (wet+dry) deposition. The ratio is calculated as $(\text{NH}_x \text{ deposition}) / (\text{NO}_y + \text{NH}_x \text{ deposition})$.

Table 2. Intercomparison of HTAP II MMM performance with previous project on dry deposition. The unit is mg (N or S) $\text{m}^{-2} \text{yr}^{-1}$. S dry deposition is the sum of SO_2 and SO_4^{2-} dry deposition. N dry deposition is the sum of HNO_3 , NO_3^- and NH_4^+ dry deposition (not include NO_2 and NH_3 deposition).
