20 **Abstract.** While the elevated ambient levels of particulate matters with aerodynamic diameter of 2.5 micrometers or less (PM_{2.5}) are alleviated largely with the implementation of effective emission control measures, an opposite trend with a rapid increase is seen in surface ozone (O₃) in the North China Plain (NCP) region over the past several years. It is critical to determine the real culprit causing such a large increase in surface O₃. In this study, seven-year surface observations and satellite retrieval data are
25 analyzed to determine the long-term change in surface O₃ as well as driving factors. Results indicate that anthropogenic emission control strategies and changes in aerosol concentrations as well as aerosol optical properties such as single-scattering albedo (SSA) are the most important factors driving such a large increase in surface O₃. Numerical simulations with National Center for Atmospheric Research (NCAR) Master Mechanism (MM) model suggest that reduction of O₃ precursor emissions and aerosol radiative
30 effect accounted for 45 % and 23 % of the total change in surface O₃ in summertime during 2013–2019, respectively. Planetary boundary layer (PBL) height with an increase of 0.21 km and surface air

temperature with an increase of 2.1 °C contributed 18 % and 12 % to the total change in surface O₃, respectively. The combined effect of these factor was responsible for the rest change. Decrease in SSA or strengthened absorption property of aerosols may offset the impact of AOD reduction on surface O₃ substantially. While the MM model enables quantification of individual factor's percentage contributions, it requires further refinement with aerosol chemistry included in the future investigation. The study indicates an important role of aerosol radiative effect in development of more effective emission control strategies on reduction of ambient levels of O₃ as well as alleviation of national air quality standard exceedance events.

40 **1 Introduction**

Elevated ambient levels of ozone (O₃) are of great concern due to their important impact on human health, ecosystem productivity, atmospheric chemistry, and climate change (Monks et al., 2015; Tai et al., 2014; Tan et al., 2019). O₃ is produced by a series of photochemical reactions involving nitrogen oxides (NO_x = NO + NO₂) and volatile organic compounds (VOCs) in the presence of solar radiation. Ambient levels of O₃ are highly dependent on emissions of O₃ precursors, solar radiation, and other physical processes such as regional and vertical transport (Sun et al., 2018; Ni et al., 2018; Liu et al., 2019; Wang et al., 2016b). While O₃ concentrations show a steady decreasing trend in Europe and North America, an opposite trend with an accelerating increase rate is observed in China (Lu et al., 2018; Li et al., 2019a). Due to high nonlinearity of O₃-NO_x-VOCs relationship and complexity of processes governing ambient levels of O₃, a large uncertainty remains in the determination of impact of different driving factors on changes in surface O₃ concentrations under the polluted atmospheric conditions. Thus, accurate quantification of relative contributions of individual factors to the large increase in surface O₃ concentrations over the heavily polluted regions such as China continues to represent one of major challenges to research communities and government policy makers.

55 Anthropogenic emissions are the key in driving change in surface O₃. With rapid development of industrialization and urbanization, anthropogenic emissions of NO_x and VOCs, two major precursors of O₃ formation have been increasing significantly in China over the past several decades (Zeng et al., 2019). For instance, tropospheric columns of NO₂ (TCNO₂), an indicator of anthropogenic emission intensity of NO_x were increased by 307 % in Beijing from 1996 to 2011 (Huang et al., 2013), which caused a strong

60 increase trend of O_3 in the lower troposphere. Meanwhile, an increase in surface O_3 at a rate of $2\% a^{-1}$
was observed in Beijing from 1995 to 2005 (Ding et al., 2007), and a similar increase with $1\text{--}2\text{ ppb } a^{-1}$
was monitored at urban and remote sites in eastern China (Sun et al., 2016; Gao et al., 2017; Ma et al.,
2016; Tang et al., 2009). However, little light was shed on change in surface O_3 as compared to its
counterpart $PM_{2.5}$ which was elevated to the severe pollution level in eastern China especially over the
65 North China Plain (NCP) region (Zeng et al., 2019; Zhai et al., 2019). The severity of $PM_{2.5}$ pollution
has been largely alleviated after the stringent emission control strategies were implemented by Chinese
governments at national level in 2013 (Zeng et al., 2019). According to the estimate by Multi-resolution
Emission Inventory in China (MEIC), anthropogenic emissions of $PM_{2.5}$ decreased by approximately
60 %, NO_x emissions decreased by 21 %, significant reductions were also seen in other air pollutants
70 such as SO_2 but not for VOCs which showed an increase of 2 % instead over the period of 2013–2017
(Zheng et al., 2018). As a result, monthly mean $PM_{2.5}$ concentrations decreased by 41 % for the Beijing-
Tianjin-Hebei (BTH) region which is similar to the NCP region presented in this study, and aerosol
optical depth (AOD) was reduced by 20 % in eastern China (Li et al., 2019a). However, an opposite
trend with an accelerating increase rate of O_3 was observed in the NCP region during this period (Lu et
75 al., 2018; Cooper et al., 2014). The fact that O_3 formation was dominated by VOC-sensitive regime may
partly account for such an increase in the NCP region, but it is not clear how much the change of surface
 O_3 is attributed to anthropogenic emission control efforts.

Aerosol radiative effect is another factor imposing a large constrain on change in surface O_3 . Aerosols
attenuate surface-reached solar near-ultraviolet (UV) radiation effectively and reduce photolysis rate of
80 NO_2 , a key parameter determining O_3 formation. Impact of aerosol radiative effect on photolysis rate of
 NO_2 or O_3 photochemical production is highly dependent on aerosol optical properties as described by
AOD, single-scattering albedo (SSA), and asymmetry factor. AOD is a measure of extinction of solar
beam by aerosols (e.g., dust and haze), used as a proxy of representing severity of fine particulate-matter
pollution or aerosol mass concentrations. SSA denotes the relative contributions of scattering versus
85 absorption effect to total aerosol extinction efficiency with “0” for pure absorption and “1” for pure
scattering effect. Both numerical simulations and observations showed that aerosols with UV-scattering
effect may accelerate photochemical production of O_3 but aerosols with strong absorption property (e.g.
mineral dust and soot) may inhibit O_3 production in the atmospheric boundary layer (Dickerson et al.,
1997; Mok et al., 2016). The lowest photolysis rate coefficient was closely linked with the highest AOD

90 (Liu et al., 2019; Dickerson et al., 1997). It was observed that surface $PM_{2.5}$ concentrations decreased by
41 % whereas surface O_3 increased at a rate of 3.1 ppb a^{-1} over the BTH region from 2013 to 2017 (Li
et al., 2019a). Decrease in $PM_{2.5}$ was considered as one of the important causes leading to such an increase
in surface O_3 due to additional O_3 production associated with reduced sink of hydroperoxy radicals (HO_2)
(Li et al., 2019a). They pointed out that increase in surface O_3 associated with decrease in $PM_{2.5}$ was
95 more prominent than that with reduction of NO_x emissions over the NCP region where O_3 formation was
dominated by VOC-limited regime. Liu and Wang (2020a, 2020b) found the reduction of PM emissions
increased the O_3 levels by enhancing the photolysis rates and reducing heterogeneous uptake of reactive
gases (mainly HO_2 and O_3), of which the latter is more important than the former. Similar impact
associated with aerosol radiative properties on O_3 production was observed in other regions over the
100 world. For instance, the combined effect associated with optical properties of BrC and black carbon (BC)
reduced the net change in O_3 production by up to 18 % as compared to BC alone in the Amazon Basin
(Mok et al., 2016). Thus, surface O_3 changes are dependent on not only aerosol concentrations (AOD
used as a proxy) but also aerosol optical properties such as SSA. Relative importance of different aerosol
optical property parameters to change in surface O_3 needs to be addressed.

105 NCP, the largest alluvial plain of China, is surrounded by Mountains Yanshan with main peak of 2116
meters at the north, Mountains Taihang with the highest elevation of 2882 meters at the west, Mountains
Dabie and Tianmu at the south, and bordered to Yellow Sea at the east (see Fig. 1). Such a complex terrain
is not conducive to dispersion and dilution of air pollutants and makes them be trapped easily. Meanwhile,
the total energy consumption was increased by more than five times from 1985 to 2016 (Zeng et al.,
110 2019). NCP has become one of the most polluted regions in China. The highest $PM_{2.5}$ concentration
reached to $900 \mu\text{g} \cdot \text{m}^{-3}$ during winter and heavy $PM_{2.5}$ pollution events was the major concern to air
quality during that period (Gu, 2013; An et al., 2019), but surface $PM_{2.5}$ concentrations have reduced
substantially. Meanwhile, O_3 exceedance events became more frequent and more serious in the NCP
region (Zhang et al., 2015; Lang et al., 2017; Zhai et al., 2019). Hourly surface O_3 concentrations went
115 up to 150.0 ppb and the increase rate reached to 3.1 ppb a^{-1} , much higher than those observed in other
polluted regions such as Yangtze River Delta (YRD) and Pearl River Delta (PRD) in China (Li et al.,
2019a; Lyu et al., 2019). The elevated surface O_3 has become an emerging critical air quality issue in this
region (Wang et al., 2006; Shi et al., 2015). Understanding of the factors driving such a rise in surface
 O_3 becomes a very hot topic (Li et al., 2019a; Li et al., 2019b). However, most of the related studies are

120 limited to the contributions of atmospheric chemistry and changes in O₃ precursors' emissions. Relative
importance of aerosol radiative effect associated with substantial decrease in aerosols or PM_{2.5} and
meteorological variability to the enhancement of surface O₃ is not well qualified.

In this study, seven-year air quality observational data provided by the China National Environmental
Monitoring Center (CNEMC) Network are examined to determine the temporal and spatial variations in
125 surface O₃ over the NCP region over the period of 2013–2019. A series of analyses are presented to
investigate the long-term change trend of surface O₃ and the statistical relationships with NO_x and VOCs
emissions, meteorological variables, and aerosol radiative optical property parameters. A box model with
Master Mechanism (MM) then is utilized to determine the response of surface O₃ to the key driving
factors. The specific objectives include 1) to identify the key factors driving the increase in surface O₃
130 over NCP, the most polluted region in China; 2) to quantify the relative contributions of anthropogenic
emissions (e.g., NO_x and VOCs), aerosol concentrations, aerosol optical properties, and meteorological
variability to the increase in surface O₃ in summertime during 2013–2019.

2 Data and Methods

2.1 Observational data

135 Data used in this study include hourly-averaged surface observations of O₃ and PM_{2.5} from 2013 to 2019
provided by the CNEMC (<http://106.37.208.233:20035/>). UV data measured at the Yucheng site (i.e.,
YCA, 116.57° E, 36.87° N) in the NCP region are obtained from the Chinese Ecosystem Research
Network (<http://www.cern.ac.cn/>) from years 2013 to 2016. AOD is derived from the monthly level-3
product of the Moderate Resolution Imaging Spectroradiometer (MODIS) instrument aboard the Aqua
140 satellite, reported at 550-nm wavelength with resolutions of 1° × 1° (Platnick, 2015). TCNO₂ data are
retrieved from the daily level-3 products of the Ozone Monitor Instrument (OMI) aboard the Aura
satellite with resolutions of 0.25° × 0.25° (Nickolay A. Krotkov, 2019). Short-wave radiation data are
provided by Land Data Assimilation System (FLDAS) (NASA, 2018) at resolutions of 0.1° × 0.1°. SSA
retrieved from OMI/Aura Near UV Aerosol Optical Depth and Single Scattering Albedo V003
145 (OMAERUV) (Torres, 2006) at 388 nm are used to evaluate the impact of aerosol scattering/absorption
properties on change in surface O₃. Daily max temperature at 2 m (T_{2max}), 10 m wind speed and the
planetary boundary layer height (PBLH) are derived from the Modern-Era Retrospective Analysis for

Research and Applications version 2 (MERRA-2) reanalysis data at horizontal resolutions of $0.5^\circ \times 0.625^\circ$ (Global Modeling and Assimilation Office, 2015).

150 2.2 Model description and configurations

The MM model is utilized to quantify the relative contributions of anthropogenic emissions and aerosol optical and radiative properties to the change in surface O_3 . The MM is a chemistry box model, originally developed and updated by the scientists at National Center for Atmospheric Research (NCAR). It includes a detailed and flexible gas phase chemical mechanism consisting of approximately 5000
155 reactions for simulating temporal variations in chemical species of interest. The hydrocarbon chemistry in the MM is treated explicitly with photo-oxidation of partly oxygenated organic species included. Alkanes, alkenes and aromatics are considered as initial hydrocarbon reagents in the gas-phase mechanism. The Gear-type solver is used in the MM model to handle so large numbers of chemical reactions and species and the integration time steps varied during the simulations (Madronich and Calvert,
160 1989). The TUV model is called by the MM model for update of chemical reaction rates every fifteen minutes. This model computes time-dependent chemical evolution of an air parcel initialized with a known composition, assuming no additional emissions, no dilution and no heterogeneous processes. The MM model has been widely used to investigate impact of different factors such as emissions, chemistry, and meteorological conditions on simulations of O_3 and other chemical species (Liu et al., 2019; Geng
165 et al., 2007).

Photolysis rate $j(NO_2)$ is calculated by using the Tropospheric Ultraviolet and Visible (TUV) radiation model which is embedded into the NCAR MM (Madronich S., 1999). In the fully-coupled system, the TUV is called by the MM model for update of photolysis rates of NO_2 and other chemical species (e.g., H_2O_2 , O_3 , NO_3 , N_2O_5) every 15 minutes dynamically. The TUV model is initialized with the monthly
170 means of AOD, SSA, and total columns of O_3 retrieved from satellite measurements as well as other meteorological parameters such as cloud fractions at the central point of NCP ($36^\circ N$, $117.5^\circ E$) in June.

HO_2 radicals are important to O_3 formation. The role of HO_2 radicals can be determined by the following reactions.

where $h\nu$ represents ultraviolet radiation at the wavelengths of 200–400 nm. The MM model has a
175 capability of quantifying the role of radicals in O_3 formations under different pollution conditions.

The MM simulations are conducted for the predefined box as shown in Fig. 1 to represent ensemble
mean behaviors and responses of the model to changes of different model inputs over the NCP region.
The 24-hr simulations are conducted with the initial hour at 00z local time (LT). The inputs of the
simulations include meteorological data (e.g., air temperature, cloud, and PBLH), aerosol radiative
180 properties (i.e., AOD and SSA), and emissions. While all the meteorological inputs are generated from
observational data, the initial values of chemical species such as VOC species (e.g., Acrylic, 2-
methylbutane, Toluene, P-xylene, Isoprene), N_2 , O_2 , H_2O , NO_2 , O_3 etc. are obtained from climatology or
background values.

Emissions (NO_x and VOCs) are calculated from the MEIC emission inventory. Aerosol radiative
185 property parameters from MODIS and OMAERUV are assumed as constants for all the simulations. All
the simulations are driven by the monthly means averaged over the entire NCP region. The temporal
variations at an interval of 4 hours are included in the model inputs to represent the diurnal variations in
different meteorological variables such as $T_{2\text{max}}$ and PBLH from MERRA-2 reanalysis.

Six groups with a total of sixteen numerical experiments with the MM model are designed to quantify
190 the roles of different factors in driving change in O_3 concentrations (Table 1). Case A stands for the base
that the emissions were generated from MEIC in base year 2012 (<http://www.meicmodel.org/>) with an
adjustment for year-2013 use, and the spatial distributions of NO_x and VOCs are presented in Fig. S1.
Case B represents a scenario for year 2019 with NO_x and VOCs emission changes by -35% and $+10\%$
with respect to the case in year 2013, respectively. The changes in NO_x emissions (-35%) and VOCs
195 emissions ($+10\%$) in 2019 were obtained by extrapolating their respective changes during the period
from 2013 to 2017 (Li et al., 2019a). Case C1 denotes a scenario with AOD decreased from 1.0 (i.e., the
case for year 2013) to 0.75 (i.e., for year 2019) according to MODIS measurements and other six
members in group C are used to examine the impact of varying AOD on the change in surface O_3 . Case
D1 is the one with a change of SSA from 0.95 (year 2013) to 0.93 (year 2019). Case E is a scenario with
200 $T_{2\text{max}}$ increase from $29.9\text{ }^\circ\text{C}$ in 2013 to $32.0\text{ }^\circ\text{C}$ in 2019 based on regional average calculated with the
MERRA-2 reanalysis in the NCP region. Case F is designed to assess the impact of the increased PBLH

(i.e., increase from 0.76 km in 2013 to 0.97 km in 2019) on surface O₃ change in the NCP region. Case G is for the situation mimic for year 2019 representing the combined effect of changes in emissions, AOD, SSA, T_{2max}, and PBLH. 24-hr simulations are completed for each case to quantify the contributions of individual factors to the changes in surface O₃ from 2013 to 2019. More details of the numerical experiments are presented in Table 1.

3 Results and Discussion

3.1 Spatiotemporal variations in surface O₃, PM_{2.5}, AOD, and TCNO₂

Figure 2 shows a comparison of spatially distributed monthly means of the maximum daily 8-h average (MDA8) O₃, 24-h average PM_{2.5}, AOD, and TCNO₂ over the eastern China in June between 2013 and 2019 derived from in-situ and satellite observations. It is clear that NCP was the most polluted region with the highest values of MDA8 O₃, PM_{2.5}, AOD, and TCNO₂ over the past decade. 24-h average PM_{2.5} concentrations were higher than 75.0 μg m⁻³ (the Grade II National Ambient Air Quality Standard, NAAQS defined for residential areas) at most of the monitoring stations across the NCP region in June 2013. The highest 24-h average PM_{2.5} reached to 766.0 μg m⁻³ and the corresponding AOD was 1.0. As compared to the well-established monitoring network of PM_{2.5}, observational sites for O₃ were pretty sparse except for the BTH, YRD, and PRD across the eastern China in 2013. While the TCNO₂ was 2 times higher than that observed in North America (Stavrakou et al., 2008), the exceedance events of the MDA8 O₃ were not frequently observed across eastern China in 2013. PM_{2.5} was the major air pollutant in the NCP region during that time period.

PM_{2.5} concentrations, AOD, and TCNO₂ have been reduced substantially as a result of the implementation of strict anthropogenic emission reduction policy in 2013. For instance, monthly mean of PM_{2.5} concentrations decreased from 95.5 μg m⁻³ to 33.2 μg m⁻³ with a percentage reduction of 65 %. Monthly mean AOD was reduced from 1.0 in 2013 to 0.75 in 2019, indicating that PM_{2.5} continued to decrease at a rate of -10 ~ -11 % a⁻¹ which was similar to that during 2013–2017 (Li et al., 2019a). On the other hand, a rapid increase in surface O₃ concentrations was observed in the NCP region over the past several years. The hot spots with the MDA8 O₃ higher than 75.0 ppb were extended to the entire NCP as well as the neighbor regions in 2019 (Fig. 2b). The highest MDA8 O₃ reached to 112.8 ppb in 2018, which was even higher than the level (110.0 ppb) observed in Los Angeles (Lin et al., 2017). As

230 compared to the cases observed in 2017 (Li et al., 2019a; Li et al., 2019b), air pollution events with higher surface O_3 became more severe and more frequent. The frequency of NAAQS exceedance events for surface MDA8 O_3 (i.e., greater than $160 \mu g m^{-3}$) in June increased from 30 % in 2013 to 63 % in 2019. Here percentage represents the proportion of MDA8 exceedance days to a total of 30 days (i.e., June).

235 Reduction in NO_x emissions and slight increase in VOC emissions could be part of the reasons causing such an increase over the NCP region where O_3 formation was dominated by VOC-limited regime. Meanwhile, Li et al. (2019a) attributed the increase to aerosol chemistry that removal of HO_2 radicals was reduced and more O_3 production was promoted. On the other hand, attenuation of UV radiation became less evident as $PM_{2.5}$ or AOD continually decreased. Strengthening UV radiation may accelerate
240 photolysis of NO_2 and eventually led to more O_3 production. Importance of aerosol radiative effect in the increase in surface O_3 via the way of accelerating photolysis of NO_2 can be further evaluated through numerical experiments.

Meteorological conditions are another critical factor affecting O_3 production. Typically, higher air temperature is responsible for higher photochemical reaction rates and more O_3 photochemical
245 production (Porter and Heald, 2019). As shown in Fig. 3, NCP was the hottest spot region with T_{2max} which was about $4.0 \text{ }^\circ C$ higher than that in the neighbor regions. In addition, increase rate of T_{2max} in the NCP was larger than that observed in other regions in eastern China. T_{2max} and surface-reaching shortwave radiation increased by 3 % and 7 %, respectively, over the past several years. In addition to man-made factors such as urbanization and industrialization, decrease in aerosols (e.g., $PM_{2.5}$ and AOD)
250 could be an important factor driving such a rise in air temperature due to weakening aerosol radiative effect.

3.2 Yearly changes in surface O_3 during 2013–2019 and driving factors

As presented above, NCP was the most polluted region with extremely high ambient levels of air pollutants. Surface O_3 showed a rapid increase over the period from 2013 to 2019 while $PM_{2.5}$ and other
255 pollutants such as NO_x experienced a significant reduction. O_3 has become a major air quality concern in summer. June was the month with the highest monthly mean MDA8 O_3 concentrations (Fig. S2). In this section, we attempt to investigate the yearly change rate and to identify the factors that drove such a

large increase in surface O₃ over the NCP region throughout the period of 2013–2019.

Figure 4 shows the yearly changes in monthly means of MDA8 O₃, PM_{2.5}, AOD, SSA, TCNO₂, T_{2max},
260 and PBLH over the NCP region in June from 2013 to 2019. The change in monthly mean of surface
MDA8 O₃ showed an opposite trend to that of PM_{2.5} concentrations and other air pollutants. The increase
rate of monthly mean MDA8 O₃ (4.6 ppb a⁻¹) during 2013–2019 was much higher than that observed in
the same region during the period of 2005–2015 (1.1 ppb a⁻¹) (Ma et al., 2016), and other regions such
as Mountain Tai, YRD, Hong Kong, and North America where the changes were less than 2.1 ppb a⁻¹
265 during the similar time period (e.g., Sun et al., 2016; Gao et al., 2017; Wang et al., 2017; Xu et al., 2019).
At the same time, a large decrease can be found from the time series of PM_{2.5}, AOD, and TCNO₂. It is
noted that SSA also showed a decreasing trend (Fig. 4e). Decrease in SSA was likely due to the fact that
reduction of inorganic aerosols (e.g., sulfate and nitrate) was larger than that of carbonaceous ones
(Zhang et al., 2020). Another noticed feature is that MDA8 O₃ showed a decreasing trend in 2019 relative
270 to 2018, which was opposite to that during 2013–2018 (Fig. 4a). It is worth to witness the change trend
in the coming years.

To understand the factors driving the change in surface O₃, a series of scatter plots are presented to
examine the relationships between the surface MAD8 O₃ and individual factors such as aerosol optical
properties (i.e., AOD and SSA), TCNO₂, T_{2max}, and surface-reaching short-wave radiation over the past
275 seven years in June (Fig. 5). The values discussed here represent the monthly means. MAD8 O₃ showed
two different regimes with an opposite dependence of O₃ formation on PM_{2.5} concentrations. The first
regime showed a decrease trend with increasing surface PM_{2.5} when PM_{2.5} concentrations were less than
approximately 140.0 μg m⁻³ whereas the second one showed no trend with increasing PM_{2.5} when
PM_{2.5} concentrations were higher than 140.0 μg m⁻³. The first regime was highly related to aerosol
280 radiative effect, which has been discussed above. For the 2nd regime, the impact of aerosol radiative effect
on surface O₃ photochemical production seemed very minor or even negligible. Instead, O₃ production
was suppressed significantly and MAD8 O₃ concentrations were less than 20.0 ppb. In this case, removal
of surface O₃ through titration of NO was not effective and surface O₃ showed an increase rather than a
decrease trend with increasing NO_x concentrations under the strong NO_x conditions as indicated by
285 TCNO₂ higher than 40–45 × 10¹⁵ (cm⁻²) in the troposphere. Here the threshold value of 140.0 μg m⁻³
represents an observed reality in this region but it needs to investigate whether such a threshold value
exists in other regions.

Figures 5d–e further demonstrate the critical role of meteorological factors in change of surface O₃. MDA8 O₃ showed a near linear increasing trend with increasing T_{2max} and surface-reaching shortwave radiation with respective linear regression correlation coefficients of 0.88 and 0.93. Increase in T_{2max} and strengthening shortwave radiation caused by decrease in PM_{2.5} (a proxy of aerosols) played a positive role in driving the increase in surface O₃ in the NCP region. On the other hand, MDA8 O₃ showed a decrease trend with 10 m wind speed (Fig. 5f). That may explain why improvement of stagnation atmospheric conditions may alleviate severity of surface O₃ pollution to some extents.

Enhancement of UV radiation resulting from reduction in surface PM_{2.5} represents one of important mechanisms in driving increase in surface O₃ concentrations. It can be further illustrated by Fig. 6. While UV radiation displays a nonlinear decreasing trend with surface PM_{2.5} concentrations, surface O₃ (hourly) shows a near linear increasing trend with surface-reached UV radiation. UV radiation attenuation approaches to a constant with a value of 0.1–0.3 MJ m⁻² when surface PM_{2.5} concentrations reach to around 300 μg m⁻³ or above.

Analyses presented above demonstrate that all the exceedance events of MDA8 are observed under conditions with PM_{2.5} less than 60 μg m⁻³, TCNO₂ of equal to or less than 5.0 × 10¹⁵ (cm⁻²), T_{2max} higher than 28.0 °C, and surface-reaching shortwave radiation stronger than 250.0 W m⁻². Reduction in aerosols (e.g., surface PM_{2.5} as a proxy) concentrations may strengthen UV radiation, increase T_{2max}, and eventually promote more surface O₃ production.

3.3 Relative contributions of different driving factors to increase in surface O₃

In this section, the box model MM is utilized to quantify the relative contributions of individual driving factors to the increase in surface O₃ over the NCP region during 2013–2019. A simulation-observation comparison is presented to evaluate the performance of the MM model on simulations of surface O₃ (Fig. 7), of which the O₃ observations averaged over all the stations in NCP is considered as the standard observed concentrations. The simulated O₃ peak was about one hour later than the observation, which was likely due to uncertainty of emission inventory and other meteorological factors. Overall, the MM model was able to mimic the observed variation pattern and peak value as indicated by the correlation coefficient of 0.95 between simulated and observed O₃.

A series of numerical experiments were then completed with the MM model to quantify the relative

contributions of anthropogenic emissions (i.e., NO_x and VOCs), AOD, SSA, air temperature, and PBLH to the change in surface O_3 over the NCP region during 2013–2019. The results are presented in Table 2. The changes in emissions of O_3 -precursors (i.e., NO_x and VOCs) (i.e., Case B) and decrease of AOD (i.e., Case C1) were the two major contributors with their respective positive contributions of 45 % and 70 %
320 to the increment in surface O_3 . But increase in surface O_3 associated with AOD reduction was largely offset by the reduction in SSA. Moreover, air temperature played a non-negligible role and the increase in $T_{2\text{max}}$ accounted for 12 % of surface- O_3 enhancement (Case E). Meanwhile, the increase of PBLHs also contributed about 18 % to the increment in surface O_3 (Case F). As indicated by Case G, the combined effect by multiple factors was larger than the simple summation of individual factor's
325 contributions or the total percentage contributions by individual factor was less than 100 %. This is likely due to the fact that O_3 production is not the linear function of individual factor's contribution. Complex interplay among different factors may account for rest of the increase (i.e., 2 %).

It is not surprised that reduction in NO_x emissions brought about increase in surface O_3 since O_3 formation was dominated by VOC-limited regime in most parts of the NCP region. Several numerical
330 experiments were conducted to understand the mechanism of reduced $\text{PM}_{2.5}$ or AOD facilitating the increase in surface O_3 . It is known that photolysis rate of NO_2 , $j(\text{NO}_2)$ plays a critical role in O_3 formation. Parameter $j(\text{NO}_2)$ was highly dependent on aerosol optical properties such as AOD and SSA, as well as solar zenith angle (θ) (Dickerson et al., 1997). As shown in Fig. 8a, decreasing AOD was conducive to photolysis of NO_2 due to reduction of attenuated UV radiation entering the PBL. However, weakened
335 scattering or strengthened absorption property of aerosols (i.e., reduced SSA) may attenuate the UV entering the PBL, decelerating photolysis of NO_2 . Thus, decrease in SSA may counteract the impact associated with decrease in AOD, which may slow down the increase in surface O_3 to some extents. In addition, $j(\text{NO}_2)$ showed the highest value at noontime ($\theta = 0^\circ$ or $\sec \theta = 1$) and tended to decrease when θ became larger (i.e., early morning or late afternoon). Figure 8b further demonstrates that O_3
340 formation or MDA8 O_3 showed a near linear increasing trend with $j(\text{NO}_2)$. While decrease in $\text{PM}_{2.5}$ concentrations or AOD strengthened the UV amount entering the PBL reduction in SSA may counteract impact of decreased AOD partially. But impact of AOD outpaced that of SSA. Thus, surface O_3 (e.g., MDA8 O_3) still showed a large increase with the combined effect of AOD and SSA over the past several years.

345 Now let us turn our attention to O_3 -chemistry in the varying polluted region. As illustrated in Fig. 9,

HO₂ radicals were sensitive to aerosol properties (i.e., AOD and SSA) but the sensitivity was highly
relied on the solar zenith angle (θ). HO₂ radical was more sensitive to AOD or SSA in the afternoon than
in the morning while photolysis rate of HO₂ is more sensitive to AOD or SSA. It is noted that higher net
O₃ production is highly associated with the faster decrease in J(O₃) than J(NO₂) in the afternoon
350 (Gerasopoulos et al., 2006). HO₂ radical abundance reduced as aerosol optical property became more
absorptive. This indicates that decrease in SSA may cause reduction of HO₂, less NO₂, and then less O₃
production. The HO₂ peak hour was matched well with that of O₃ peak (around 15 p.m. LT), further
confirming its important role in O₃ formation. Decrease in AOD may accelerate production of HO₂
radicals or slow down their sink, which was conducive to production of NO₂ (Li et al., 2019a) but
355 decrease in SSA may offset its impact if aerosols show strong absorption property. Meanwhile,
strengthened UV associated with weakened aerosol radiative effect was conducive to photolysis of NO₂.
As a result, more O₃ is produced. This accounted for substantial increase in surface O₃ while PM_{2.5}
decreased over the past several years (2013 to 2019). The results are consistent with the finding by Li et
al. (2019a).

360 **4 Discussions**

In this study, a box model NCAR MM with the detailed NO_x-VOC-O₃ chemistry included is utilized to
quantify percentage contributions of emissions, aerosol optical properties, and meteorological
variabilities to increase in surface O₃ over the NCP region during 2013–2019. The findings may provide
more scientific evidence to policy makers on developing more effective control strategies on reduction
365 in ambient levels of O₃ as well as exceedance events. However, three points deserve further discussions.

First, the impact of aerosol radiative effect on surface O₃ formation is dependent on not only aerosol
abundance (i.e., AOD) but also aerosol scattering/absorption property (i.e., SSA). Their impacts can be
offset to some extents when AOD and SSA show the same change trend (either increase or decrease) or
can be strengthened substantially when both AOD and SSA show an opposite change trend. Here the
370 study on the NCP region represents the first case since both AOD and SSA showed a decrease trend over
the past several years. Even so, the combined impact of aerosol radiative effect due to reductions in AOD
and SSA still contributed 23% of the total change in surface O₃ in the NCP over the past several years.
This reminds us that the impact of aerosol radiative effect could be more substantial if both AOD and

SSA show an opposite change trend. Moreover, as compared to impact of change in AOD on surface O₃ formation (e.g., Dickerson et al., 1997; Wang et al., 2016a; Xing et al., 2015; Xing et al., 2017), studies on impact of change in SSA on surface O₃ formation are fewer (Dickerson et al., 1997; Mok et al., 2016). Thus, changes of individual aerosol radiative property parameters must be addressed carefully in order to present more accurate quantification of impact of aerosol radiative effect on change in surface O₃.

Second, as presented above, the MM model as a box model with the detailed O₃-NO_x-VOCs relationship allows us to quantify relative contributions of individual factors to increase in surface O₃. Overall, the model results are comparable to those by using three-dimensional (3D) chemistry and transport models (e.g., Liu and Wang 2020a, 2020b). The MM model indicates that reduction of anthropogenic emissions of NO_x was the greatest contributor (45 %) to the increase in surface O₃ in the NCP region during 2013–2019, which was larger than Li et al., (2019a) in summertime from 2013 to 2017 (about 10 %) but less than that of Sun et al. (2019) in July from 2003 to 2015 (63 %) over the eastern China. Aerosol radiative effect was ranked as the 2nd contributor to the change in surface O₃ in this region. The percentage contribution was found to be larger than that presented by other studies (Li et al., 2019a; Xing et al., 2015). This is partly because this study is focused on the impact on MDA8 O₃ whereas their studies investigated the impact on diurnal variations of surface O₃. In addition, Li et al., (2019a and 2019b) and Liu and Wang (2020a and 2020b) pointed out that aerosol chemistry played the most important role in the enhancement of surface O₃ in this region through modification of HO₂ radicals that produce additional O₃ formation. However, the MM model does not include aqueous-phase chemistry that has been implemented in the 3D meteorology/chemistry models (e.g., Li et al., 2019a; Liu and Wang, 2020a, 2020b). Thus, inclusion of aerosol chemistry in a box model like MM is necessary to provide more accurate assessment of impact of aerosol radiative effect on surface O₃ change.

Third, as compared to 3D meteorology/chemistry coupling model(s), box model does not include complex physical processes such as regional transport, vertical diffusion, and cloud formation, etc. Computational resource and workload that a box model requires are much less than that a 3D chemical transport model needs. This may allow us to complete a series of designed numerical experiments to quantify the roles of individual factors easily with limited computational resources. It is acceptable by using a box model if terrains are relatively flat in the box, horizontal gradients of emissions and air pollutant concentrations are not strong, and transport in and out reaches a relative equilibrium state. As shown in Fig. S1 and Fig. 2, the NCP region defined in this study represents the most polluted part in

eastern China, anthropogenic emissions tend to distribute relatively uniform across the region. To this
405 extent, it is appropriate to examine O₃ formation and its response to changes of different factors such as
emissions, meteorological conditions, and aerosol radiative properties by using a box model in the NCP
region. It is reminded that some other factors such as background ozone are not included in our sensitivity
study due to their limited impact in this region, and the box model results present an ensemble-mean
behavior for the given box but need further evaluations by using a complex meteorology/chemistry
410 coupling model such as Weather Research and Forecasting model with Chemistry (WRF/Chem).

5 Summary and conclusions

In this study, seven-year long surface observational air quality data are presented together with satellite
retrieval measurements of TCNO₂, AOD and SSA to investigate long-term change trend of surface O₃
415 over the NCP region in summer from 2013 to 2019. A comprehensive statistical analysis is completed to
explore the relationship of MDA8 O₃ with PM_{2.5} concentrations, tropospheric columns of NO₂, AOD,
and meteorological variables such as T_{2max}, surface-reaching shortwave radiation, wind speed, and PBLH.
A box model representing the O₃-NO_x-VOCs relationship is then utilized to quantify the relative
contributions of different driving factors to the increase in surface O₃ in the NCP region over the period
420 of 2013–2019.

The observational analysis indicates, while PM_{2.5} concentrations continued to decrease with a rate of
9.5 $\mu\text{g m}^{-3} \text{ a}^{-1}$, surface O₃ showed an accelerated increase trend at a rate of 4.6 ppb a⁻¹ over the NCP
region during summertime from 2013 to 2019. Both decrease in PM_{2.5} and reduction in TCNO₂ are the
two key factors leading to such an increase in surface O₃. The former is closely associated with the
425 attenuation of UV entering the PBL whereas the latter is related to the fact that O₃ photochemical
production in the NCP region is dominated by VOC-limited regime. The trend analysis of satellite
retrieval measurements revealed an obvious increase in T_{2max} at the rate of 0.34 °C a⁻¹, a rapid decrease
in AOD from 1.0 in 2013 to 0.75 in 2019, and a reduction in SSA from 0.95 to 0.93. The changes of both
T_{2max} and AOD were conducive to photochemical production of O₃ whereas the variability of aerosol
430 scattering/absorption property (i.e., decrease in SSA) may largely offset the impact of AOD reduction.

The sensitivity studies with the box model MM indicate that reduction of emissions (i.e., NO_x),

meteorological conditions, and aerosol radiative effect associated with decrease in aerosol concentrations were the three most important factors in driving such a large increase in surface O_3 . They accounted for 45 %, 30 %, and 23 % of the total increase in surface O_3 , respectively over the NCP region in summertime
435 during 2013-2019. For the meteorological contribution, increases in the PBLH and air temperature (e.g., T_{2max}) were responsible for 18 % and 12 % of the total change of surface O_3 , respectively. The percentage contribution of aerosol radiative effect (23 %) represented the net changes caused by aerosol concentrations (i.e., AOD) and aerosol radiative property (scattering/absorption, SSA) (70 % vs. - 47 %). The model results further demonstrated that decrease in SSA (i.e., more absorptive) may lead to reduction
440 in HO_2 radicals and NO_2 concentrations, and then less O_3 production, which may largely counteract impact of aerosol radiative effect associated with decrease in AOD.

This study has a strong implication that development of more effective control strategies on surface O_3 reduction needs to consider impact of aerosol radiative effect as well as the change of aerosol scattering/absorption properties (i.e., AOD and SSA).

445 **Data availability:** Data used in this paper can be provided by Xiaodan Ma (xiaodanma_nuist@163.com) upon request.

Author contributions: JH came up with the original idea of this study. XM and JH designed the numerical simulations. XM conducted the data analysis and the first draft of manuscript and JH did the edit work. TZ, CL, KZ, JX and WX were involved in the scientific interpretation and discussions. All
450 the authors commented on the paper.

Competing interests: The authors declare that they have no conflict of interest.

Table 1. A summary of numerical experiments with the NCAR MM model.

Case	NO _x emission	VOCs emission	AOD	SSA	T _{2max} (°C)	PBLH (km)
A	2013*	2013*	1.0	0.95	29.9	0.76
B	2019 [†]	2019 [†]	1.0	0.95	29.9	0.76
C1	2013	2013	0.75	0.95	29.9	0.76
D1	2013	2013	1.0	0.93	29.9	0.76
E	2013	2013	1.0	0.95	32.0	0.76
F	2013	2013	1.0	0.95	29.9	0.97
G	2019	2019	0.75	0.93	32.0	0.97
C2	2013	2013	0.5	0.95	29.9	0.76
C3	2013	2013	0.6	0.95	29.9	0.76
C4	2013	2013	0.7	0.95	29.9	0.76
C5	2013	2013	0.8	0.95	29.9	0.76
C6	2013	2013	0.9	0.95	29.9	0.76
C7	2013	2013	1.1	0.95	29.9	0.76
C8	2013	2013	1.2	0.95	29.9	0.76
C9	2013	2013	1.25	0.95	29.9	0.76
D2	2013	2013	1.0	0.94	29.9	0.76

640 *Year 2013: NO_x emission is 2.0×10^{12} mole. $\text{cm}^{-2} \text{s}^{-1}$, and VOCs emission is 7.3×10^9 mole. $\text{cm}^{-2} \text{s}^{-1}$

[†]Year 2019: NO_x emission is 1.3×10^{12} mole. $\text{cm}^{-2} \text{s}^{-1}$, and VOCs emission is 8.0×10^9 mole. $\text{cm}^{-2} \text{s}^{-1}$.

645

Table 2. Relative percentage contributions of emissions (case B), AOD (case C1), SSA (case D1), air temperature (case E), and PBLH (case F) to the change in MDA8 O₃ over the NCP region during 2013–2019.

	MDA8 O ₃ (ppb)	Concentration Change (ppb)	Percentage Change (%)	Percentage Contribution (%)
A	55.35			
B	59.25	3.90	+ 7 %	+ 45 %
C1	61.46	6.11	+ 11 %	+ 70 %
D1	51.22	- 4.13	- 7 %	- 47 %
E	56.43	1.08	+ 2 %	+ 12 %
F	56.95	1.60	+ 3 %	+ 18 %
G	64.09	8.74	+ 16 %	

650

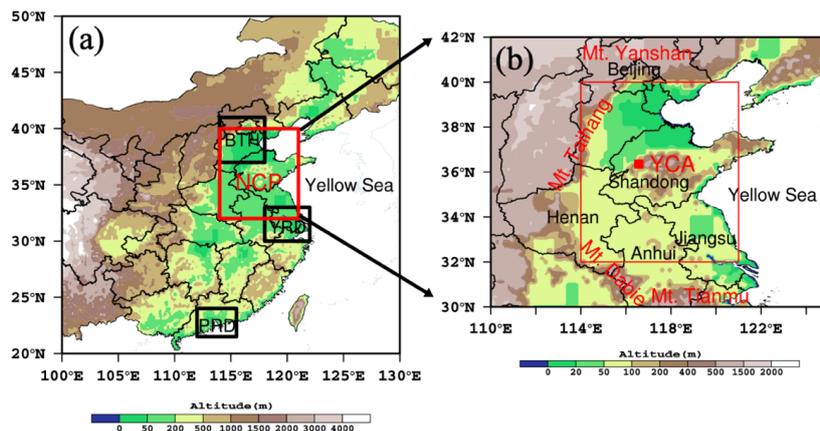

Figure 1. (a) Locations of North China Plain (NCP, 32°–40° N, 114°–121° E) and other three major air pollution regions, Beijing-Tianjin-Hebei (BTH, 37°–41° N, 114°–118° E), Yangtze River Delta (YRD, 30°–33° N, 118°–122° E), and Pearl River Delta (PRD, 21.5°–24° N, 112°–115.5° E) in China with terrain heights included and (b) location of ultraviolet (UV) radiation observational site, YCA (Yucheng site), areas covered by the NCP region and mountains surrounded.

655

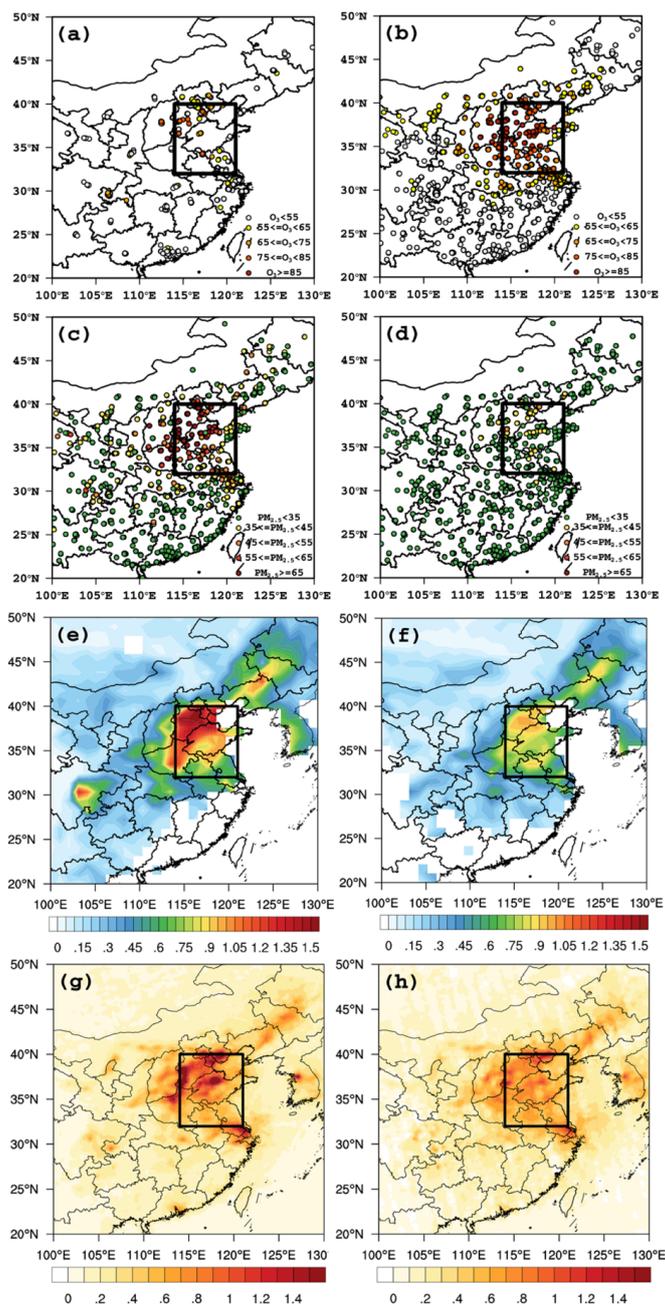

Figure 2. A comparison of spatial distributions of monthly mean of MDA8 O_3 (ppb) (a, b) and $PM_{2.5}$ ($\mu g m^{-3}$) (c, d) obtained from in-situ observations, AOD (e, f) and tropospheric column of NO_2 ($TCNO_2$, $10^{16} cm^{-2}$) (g, h) derived from satellite observations between 2013 (in left column) and 2019 (in right column) in eastern China (NCP indicated by the box).

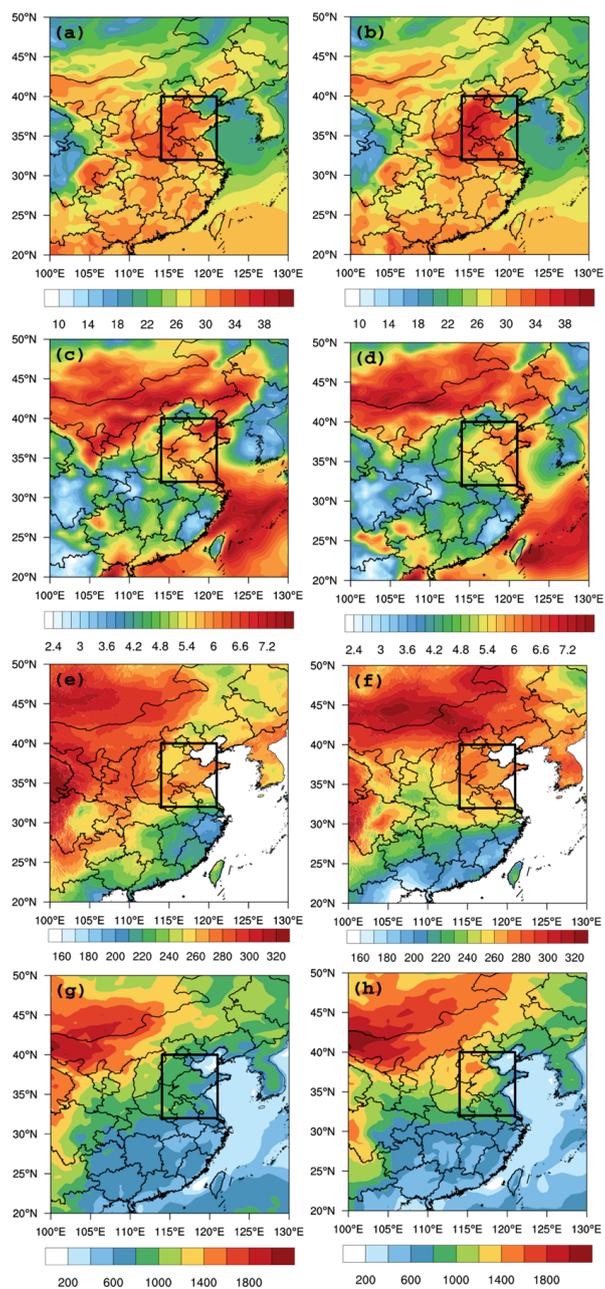

Figure 3. A comparison of spatial distributions of monthly mean of T_{2max} (°C, a and b), wind speed ($m s^{-1}$, c and d),
665 surface reaching short-wave radiation ($W m^{-2}$, e and f) and PBLH (m , g and h) between 2013 (in left column) and
2019 (in right column) in eastern China (the NCP indicated by the box).

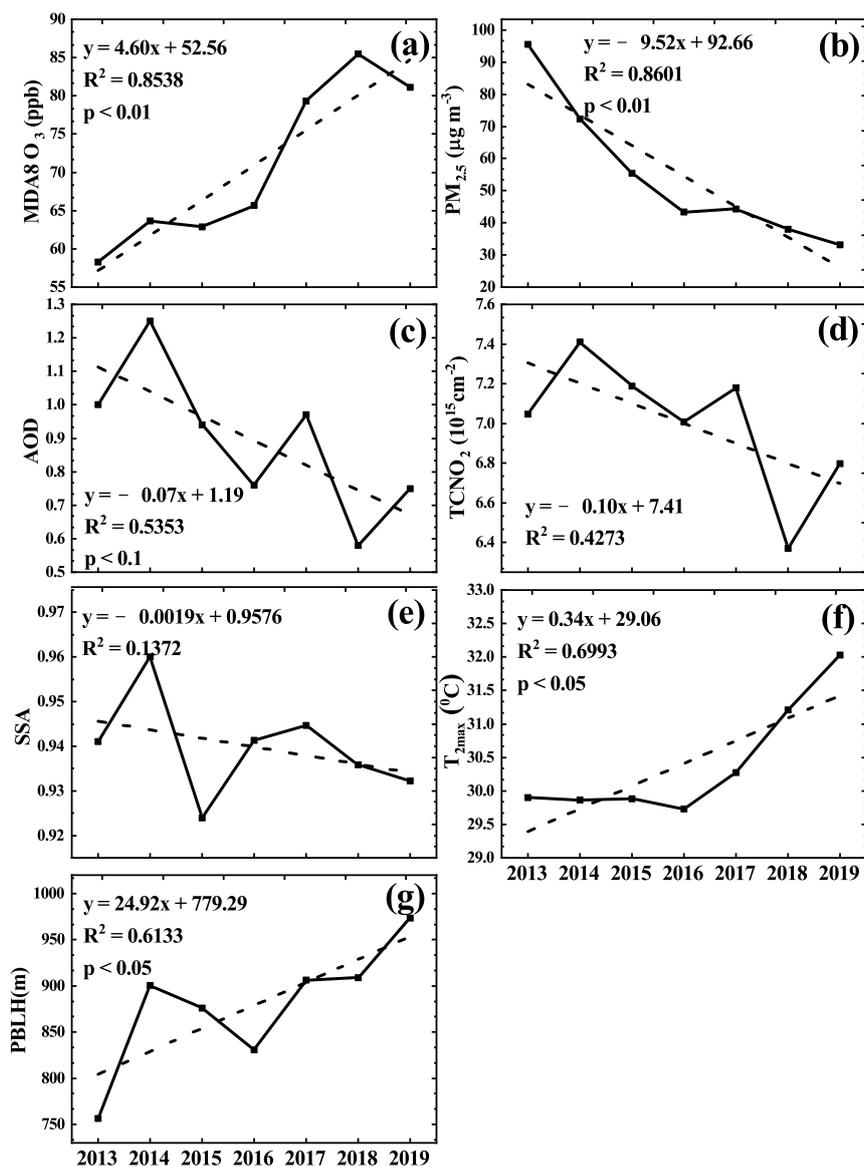

Figure 4. Long-term changes in monthly mean of (a) MDA8 O_3 , (b) $PM_{2.5}$, (c) AOD, (d) $TCNO_2$, (e) SSA, (f)

670 T_{2max} , and (g) PBLH averaged over the North China Plain in June over the period of 2013–2019.

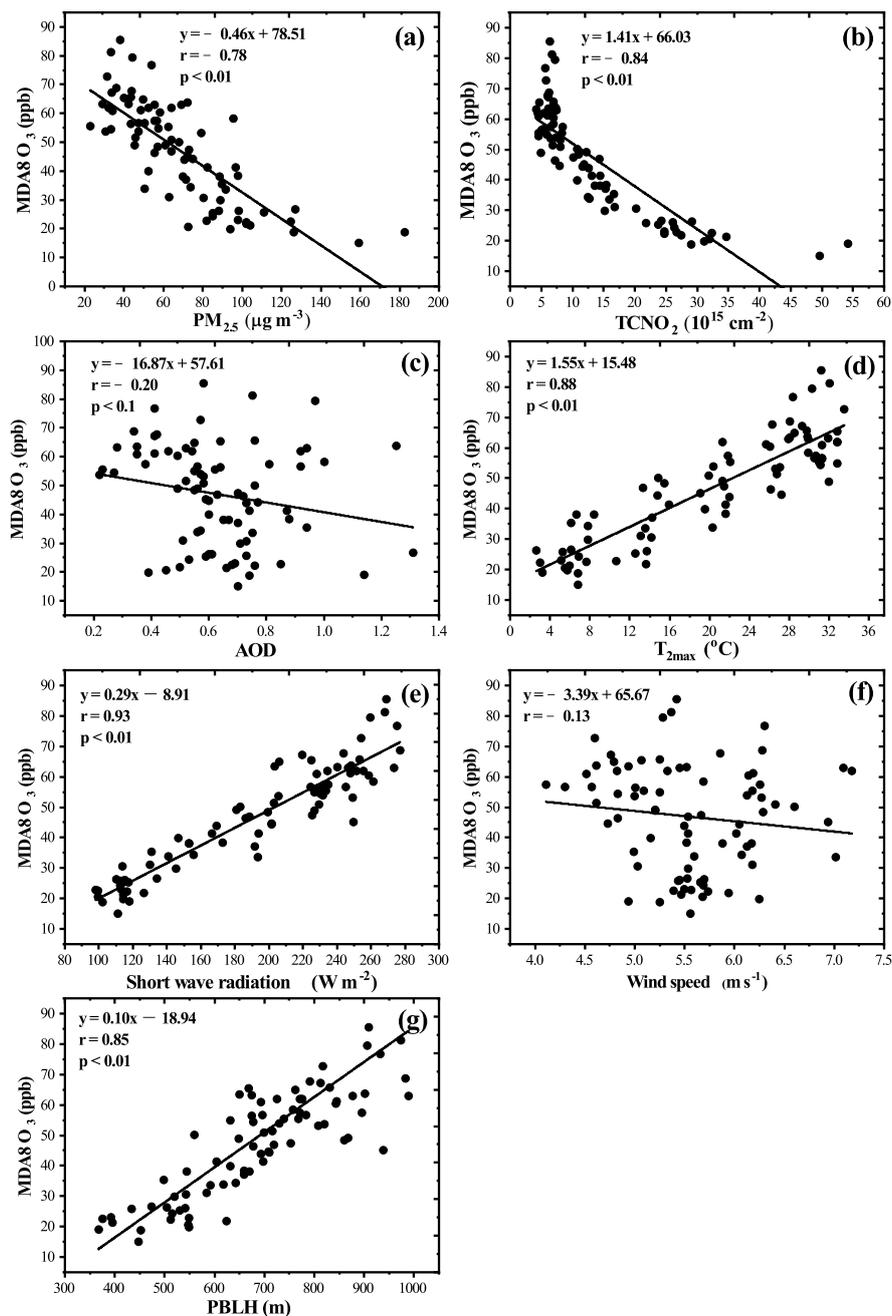

Figure 5. Response of MDA8 O₃ to (a) PM_{2.5}, (b) TCNO₂, (c) AOD, (d) T_{2max}, (e) shortwave radiation, (f) wind speed, and (g) PBLH observed in the NCP region, China during 2013–2019.

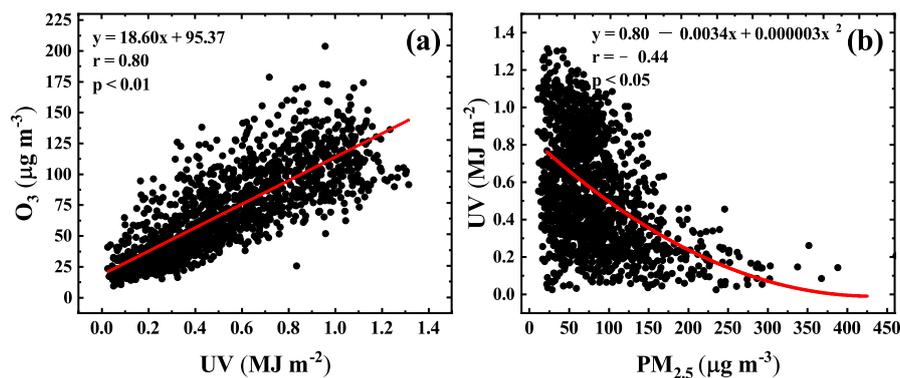

Figure 6. a) The relationships of surface O₃ concentrations (hourly) with (a) UV radiation and (b) UV radiation with PM_{2.5} concentrations based on the observations at Yucheng site during the time period of 08–17 LT in June, 2013–2016.

680

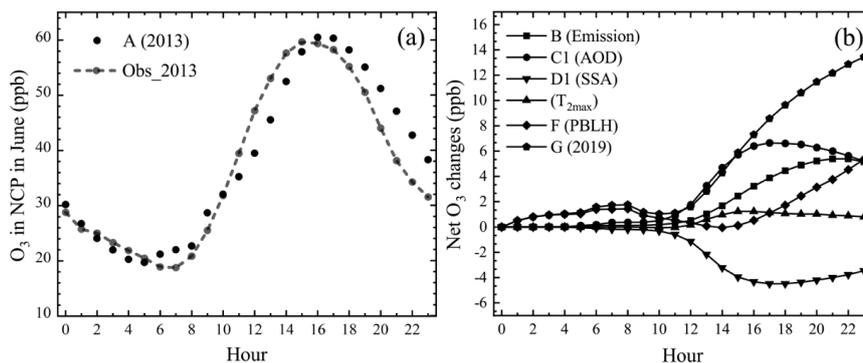

Figure 7. Comparisons of (a) regional averaged surface O₃ observations in NCP and simulated surface O₃ (A, control case) and (b) simulated net changes in O₃ among different driving-factor conditions.

685

690

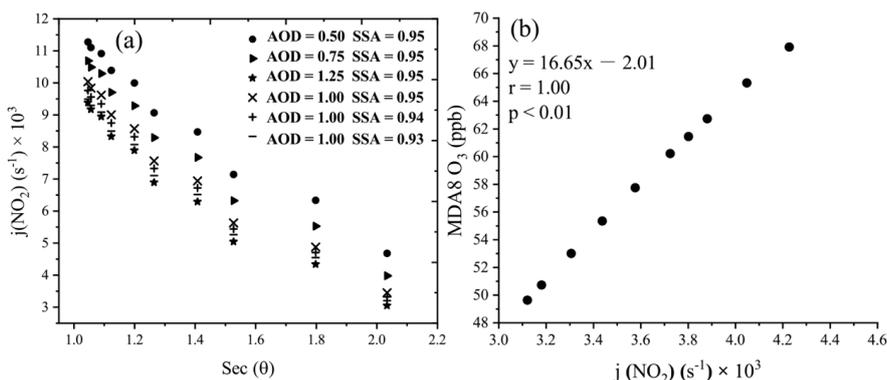

Figure 8. (a) response of photolysis rate of NO_2 , $j(\text{NO}_2)$ to different values of aerosol optical depth (AOD) and single
 695 scatter factor (SSA) and (b) change in MDA8 O_3 with $j(\text{NO}_2)$ simulated by the MM model for the cases with
 SSA=0.95 and AOD varying from 0.5 to 1.25.

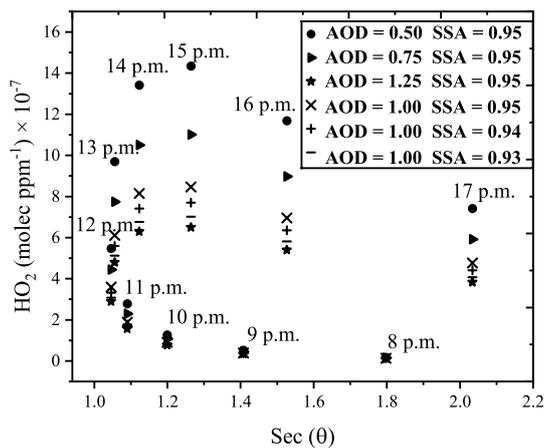

Figure 9. Response of concentrations of HO_2 to different values of aerosol optical depth (AOD) and single scatter
 700 factor (SSA).
