1 ABSTRACT

2 Ship based multi-axis differential optical absorption spectroscopy (MAX-DOAS) measurements were carried out
3 along the marginal seas of China from 19 April to 16 May 2018, to measure the vertical profiles of aerosol, NO₂ and
4 HONO. Five hot spots of tropospheric NO₂ VCDs were found in Yangtze River Delta, Taiwan straits,
5 Guangzhou-Hong Kong-Macao Greater Bay areas, Zhanjiang Port, and Qingdao port with averaged NO₂ VCDs of
6 1.07×10^{16} , 1.30×10^{16} , 7.27×10^{15} , 5.34×10^{15} , and 3.12×10^{15} molec. cm⁻², respectively. HONO performs similar
7 spatial distribution characteristics as NO₂ with averaged HONO VCDs in above five hot-spot areas of 1.01×10^{15} ,
8 7.91×10^{14} , 6.02×10^{14} , 5.36×10^{14} , and 5.17×10^{14} molec. cm⁻², respectively. The averaged near-surface NO₂
9 concentrations were 8.46 and 11.31 ppb, and the averaged near-surface HONO concentrations were 0.23 and 0.27 ppb
10 under viewing sea and viewing land observation azimuths during the whole campaign, respectively. The Chinese
11 Academy of Meteorological Sciences (CAMS) and Southern University of Science and Technology (SUST)
12 MAX-DOAS stations were selected as inland and coastal cases to further understand the impacts of relative humidity
13 (RH), temperature, and solar radiation intensity (SRI) on the heterogeneous reaction of NO₂ to form HONO in
14 different scenes. The emission ratios of $\Delta HONO / \Delta NO_x$ in sea, CAMS and SUST were $0.46 \pm 0.31\%$, $0.82 \pm$
15 0.34% , and $0.79 \pm 0.31\%$, respectively. The RH turning points in CAMS and SUST cases were all ~65% (60-70%),
16 however, two turning peaks (~60% and ~85%) of RH were found in sea cases. The HONO/NO₂ decrease along with
17 the increase of temperature, and with peak values on ~12.5°C in CAMS. The HONO/NO₂ increase along with
18 increasing temperature, and with peak values on ~31.5°C in SUST. In sea case, the HONO/NO₂ increase along with
19 the increase of temperature with a peak value on ~25.0°C under the temperature being larger than 18.0°C. That means
20 the high temperature could contribute to the secondary formation of HONO in sea atmosphere. The correlation
21 analysis between HONO and aerosol in near-surface layer illustrated the ground surface plays a more important role
22 than aerosol surface during the HONO formation process from the heterogeneous reaction of NO₂ under inland case,
23 however, aerosol surface plays a more important role during above process under coastal and sea cases. Moreover, we
24 found the HONO generation rate from NO₂ heterogeneous reaction in sea case is larger than that in inland case in
25 higher atmospheric layers above 600 m.

26 1 Introduction

27 Nitrous acid (HONO) is an important part of the atmospheric nitrogen cycle, and plays a significant role in
28 atmospheric oxidation capacity (Alicke et al., 2003; Kleffmann et al., 2005). Previous studies reported the

29 contribution of HONO photolysis to OH radicals can reach 40–60%, and even more than 80% especially in the early
30 morning (Michoud et al., 2012; Ryan et al., 2018; Xue et al., 2020). OH radicals are one of the most important
31 oxidants in the atmosphere. They can oxidize and destroy most atmospheric pollutants, such as CO, NO_x (NO+NO₂),
32 SO₂ and volatile organic compounds (VOCs), thereby further promoting the formation of secondary pollutants (ozone
33 (O₃), peroxyacetyl nitrate (PAN), and secondary aerosols, etc.), leading to serious haze pollution events (Huang et al.,
34 2014). In addition, as a nitrosating agent, HONO can produce carcinogenic nitrite amines to threat to human health
35 (Zhang et al., 2015). Therefore, a full understanding of the source and formation mechanism of HONO has very
36 important scientific significance for the study of tropospheric oxidation and the control of secondary pollution.

37 At present, the known sources of HONO mainly include direct emissions from vehicles, ships, biomass burning and
38 soil, the homogeneous reaction of NO and OH radicals, the heterogeneous reaction of NO₂ on aerosols, vegetation,
39 ground and other types of surfaces, and the photolysis of nitrate particles (NO₃⁻) (Wang et al., 2015). There are also
40 some obvious unknown HONO sources (Fu et al., 2019). The heterogeneous reaction of NO₂ as a source of HONO
41 has received continuous attention in recent years. It has been found that the heterogeneous reaction of NO₂ is one of
42 the most important sources of HONO in a variety of scenarios such as inland, coastal cities and offshore seas. Liu et al.
43 (2021) reported the contribution of heterogeneous reaction of NO₂ on aerosol surface to HONO is 19.2% in summer,
44 and this contribution of heterogeneous reaction of NO₂ on aerosol and ground surfaces to HONO can reach 54.6% in
45 winter in Beijing. Yang et al. (2021) and Zha et al. (2014) found that the generation rate of HONO through the
46 heterogeneous reaction of NO₂ under sea-wind conditions could elevate 3–4 times than that under land-wind
47 conditions in the northern coastal city of Qingdao and the southern coastal city of Hong Kong, respectively. Cui et al.
48 (2019) illustrated that the heterogeneous reaction of NO₂ on aerosol and sea surfaces is an important source of HONO
49 in East China Sea in summer. The process of HONO formed from the heterogeneous reaction of NO₂ is affected by
50 various atmospheric parameters. The relative humidity (RH), temperature, solar radiation intensity (SRI), aerosol
51 concentration and its relative surface area are the particularly important parameters. Previous works always use the
52 linear regression relationship between HONO/NO₂ and above parameters to characterize the influence of these
53 parameters on the formation of HONO through the heterogeneous reaction of NO₂. Wen et al. (2019) found that the
54 increased temperature could promote the heterogeneous reaction of NO₂ to form HONO in sea conditions. The
55 generation rate of HONO could increase rapidly, when the temperature is greater than 20 °C. Gil et al. (2019) found
56 that the HONO formed from the heterogeneous reaction of NO₂ will increase along with the increase of RH when RH
57 is less than 80% in a case of land park using deep learning forced by measurement results. Fu et al. (2019) reported
58 that RH and SRI are the main parameters driving the heterogeneous reaction of NO₂ to form HONO in Pearl River
59 Delta, and it contributes 72% of the total source of HONO. Cui et al. (2019) found that the potential of heterogeneous
60 reaction of NO₂ to form HONO will increase with the increase of particle concentration and the specific surface area
61 of single particle in coastal cities.

62 However, previous researches generally focuses on the near-surface layer of a single scene, and attentions on the
63 influence mechanism of the heterogeneous reaction of NO₂ to form HONO in vertical direction and in different sea
64 and land scenes are insufficient, which limits the comprehensive assessment to understand the sea-land differences
65 and impact mechanism of HONO formed from the heterogeneous reaction of NO₂. NO₂ could be transported from
66 inland and coastal cities to offshore seas (Tan et al., 2018). This part of NO₂ can promote the HONO formation
67 through heterogeneous reaction on the high-level aerosol and sea surfaces in the atmosphere of sea (Zhang et al.,
68 2020). The formed HONO is completely likely to be transported to land cities at night under favorable weather
69 conditions. It will affect the atmospheric oxidation and air quality, and even endanger human health. In addition, the
70 vertical distributions and values of atmospheric meteorology and aerosol parameters are significantly different in land
71 and sea scenes, which provide different conditions for the heterogeneous reaction of NO₂ to form HONO in different
72 height layers. Moreover, aerosols and NO₂ have complex evolution and transmission characteristics in vertical
73 direction. The vertical upward transport of aerosol and NO₂ can promote the HONO formation through heterogeneous
74 reaction at high altitude, and the vertical downward transport of HONO will impact the atmospheric environment near
75 the ground. The vertical observations in land-sea scenes is also helpful to distinguish the contribution of the
76 heterogeneous reaction of NO₂ on the aerosol and ground/sea surfaces (Zhang et al., 2020).

77 At present, a variety of HONO measurement techniques have been developed, which can be roughly divided into wet
78 chemical methods, spectroscopy methods, and mass spectrometry methods, in principle (Cheng et al., 2013; Bernard
79 et al., 2016; Gil et al., 2019; Guo et al., 2020; Jordan et al., 2020). However, these technical methods can only
80 measure the HONO information near the surface layer. Zhang et al. (2020) measured the vertical distribution of
81 HONO by placing wet chemical HONO samplers at different heights of tower in Beijing during spring, and found the
82 maximum value of HONO appeared at 120 m sourced from the heterogeneous reaction of NO₂ on aerosol surface
83 under haze conditions. Meng et al. (2020) also used tower by moving the IBBCEAS carried in a box at a constant
84 speed to measure the vertical profiles of HONO in Beijing during winter, and reported that the heterogeneous reaction
85 of NO₂ under the atmospheric boundary layer is an important source of HONO, especially in haze conditions.
86 However, the cost of above techniques used to measure HONO vertical profiles is too high, and the real-time and
87 continuous measurement cannot be realized. Multi-axis differential optical absorption spectroscopy (MAX-DOAS), as

88 a ground-based ultra-hyperspectral remote sensing technology, has been widely used for vertical observation of
89 atmospheric pollutants in the past two decades. Therefore, the measurement of the vertical profiles of HONO under
90 different sea-land scenes based on MAX-DOAS could provide technical supports for learning the sea-land and
91 vertical differences and the influence mechanism of the heterogeneous reaction of NO₂ to form HONO. In the past
92 five years, several researchers have carried out campaigns based on MAX-DOAS to measure the vertical profile of
93 HONO in inland and coastal areas, and revealed the sources of HONO and their contribution to atmospheric oxidation
94 at different height layers (Garcia-Nieto et al., 2018; Wang et al., 2019). There are few studies on the sources of
95 HONO at different height layers in sea scene. In this study, it will be the first time to use MAX-DOAS to study the
96 spatiotemporal distribution and the sources of HONO along the Chinese coastline, and to learn the differences of the
97 HONO formed from the heterogeneous reaction of NO₂ in different height layers and land-sea scenes.

98 2 Methods and methodologies

99 2.1 The measurement cruise

100 The ship-based atmospheric observation campaign along the marginal seas of China was carried out from 19 April to
101 16 May 2018. The latitude and longitude ranges of the entire campaign covered 21.12°N-35.89°N and
102 110.67°E-122.16°E. The detailed voyage records of the observation ship are shown in Table 1. An integrated and fully
103 automated MAX-DOAS instrument was installed aboard the stern deck of the ship (Fig. S1(a)). In order to ensure that
104 the instrument is always kept in a horizontal position, a photoelectric gyro was used. The angle between the
105 observation direction and the heading direction of the ship was always maintained at 135° during the whole campaign.
106 The telescope unit of the instrument pointed towards sea during cruise NO.3 and NO.6. The telescope unit pointed
107 towards inland during cruise NO.1, NO.4 and NO.5. During cruise NO.2, the observation telescope always pointed to
108 Chongming island. The measurement ship only sailed in daytime from 19 April to 02 May, and continuously sailed in
109 all the daytime and nighttime from 3 May to 16 May 2018. The ship docked in Daishan port on 9-10 May and no
110 observations were carried out during these two days.

111 The aim of this campaign was to learn the vertical differences of NO₂ heterogeneous reaction to produce HONO in
112 marginal seas of China and compare the influence mechanism of that in inland cities. This study will provide
113 scientific guidance for understanding regional oxidation capacity and controlling the secondary air pollution.

114 2.2 MAX-DOAS measurements

115 2.2.1 Instrument setup

116 The compact instrument consists of an ultraviolet spectrometer (AvaSpec-ULS2048L-USB2, 300-460 nm spectral
117 range, 0.6 nm spectral resolution) at a 20°C fixed temperature with a deviation of < 0.01°C, a one-dimensional CCD
118 detector (Sony ILX511, 2048 individual pixels) and a telescope unit driven by a stepper motor to collect scattered
119 sunlight from different elevation angles. The accuracy of elevation angle is < 0.1 ° and the telescope field of view
120 (open angle) is < 0.3°. A full scanning sequence consists of 11 elevation angles (1°, 2°, 3°, 4°, 5°, 6°, 8°, 10°, 15°, 30°
121 and 90°). The integration time of one individual spectrum was set to 30 s, and each scanning sequence took about 5.5
122 min. Besides, the controlling electronic devices and connecting fiber are mounted inside. The instrument is equipped
123 with a high-precision Global Position System (GPS) to record the real-time coordinated positions of the ship cruise.

124 2.2.2 Data processing and filtering

125 The MAX-DOAS measurements could be influenced by the exhaust from the measurement ship. Therefore, the data
126 contaminated by the exhaust were filtered out. As shown in Fig. S1(b), the direction and speed of the plume exhausted
127 from the ship depends on the ship direction/speed and the true wind speed/direction. Individual measurements taken
128 under unfavorable plume directions (plume directions between 45 and 135° with respect to the heading of the ship)
129 were discarded. In order to avoid the strong influence of the stratospheric absorption, the spectra measured with solar
130 zenith angle (SZA) larger than 75° were filtered out. Under these two filtering criteria, 4.9 and 8.3% of all data were
131 rejected before DOAS analysis (Xing et al., 2017, 2019, 2020).

132 2.2.3 DOAS analysis

133 The MAX-DOAS measured spectra were analyzed using the software QDOAS which is developed by BIRA-IASB
134 (<http://uv-vis.aeronomie.be/software/QDOAS/>). The DOAS fit results are the differential slant column densities
135 (DSCDs), i.e. the difference of the slant column density (SCD) between the off-zenith spectrum and the
136 corresponding zenith reference spectrum. Details of the DOAS fit settings are listed in Table 1. A typical DOAS
137 retrieval example for the oxygen dimer (O₄), nitrogen dioxide (NO₂) and nitrous acid (HONO) are shown in Fig. 1.
138 The stratospheric contribution was approximately eliminated by taking the zenith spectra of each scan as reference in
139 the DOAS analysis. Before profile retrieval, DOAS fit results of O₄, NO₂ and HONO with root mean square (RMS) of
140 residuals larger than 3×10^{-3} were filtered. Moreover, the SCD data under the color index (CI) being < 10% of the
141 thresholds obtained through fitting a fifth-order polynomial to CI data which is a function of time was filtered out, in
142 order to ensure a high signal-to-noise ratio (SNR) of the spectra. This filtering criteria remove 2.1, 3.9 and 5.3% for
143 O₄, NO₂ and HONO, respectively.

144 **2.3 Vertical profile retrieval**
145 Aerosol and trace gases (i.e., NO₂ and HONO) vertical profiles are retrieved from MAX-DOAS measurements using
146 the algorithm reported by Liu et al. (2021). The inversion algorithm is developed based on the Optical Estimation
147 Method (OEM) (Rodgers, 2000), which employs the radiative transfer model VLIDORT as the forward model. In this
148 study, an exponential decreasing a priori with a scale height of 1.0 km was used as the initial profile for both the
149 aerosol and trace gases retrieval. The surface concentrations of aerosol and trace gases were set to 0.3 km⁻¹ and 5.0
150 ppb, respectively. We assume a fix set of aerosol optical properties with asymmetry parameter of 0.69, a single
151 scattering albedo of 0.90 and ground albedo of 0.05. Moreover, the uncertainty of the aerosol and trace gases a priori
152 profile was set to 100% and the correlation length was set to 0.5 km.

153 **2.4 Ancillary data**
154 Meteorological data (including temperature, pressure, relative humidity, visibility, solar radiation intensity, wind
155 speed and wind direction) with a temporal resolution of 1 min was measured in the weather station installed on the
156 ship. NO was measured using NO analyzer (Thermo Scientific model 42i) with a 1 min time resolution. The speed of
157 the ship was calculated referred to the GPS data.

158 **3 Results and Discussion**

159 **3.1 Overview of the MAX-DOAS observation over marginal seas of China**
160 A radiative transfer model SCIATRAN was used to convert SCDs of NO₂ and HONO to their tropospheric vertical
161 column densities (VCDs). The vertical profiles of aerosol, NO₂ and HONO retrieved from MAX-DOAS, the
162 temperature and pressure vertical profiles simulated using a dynamical-chemical model (WRF-Chem), and the
163 geo-position data collected by GPS were introduced as inputs in SCIATRAN for the NO₂ and HONO air mass factor
164 (AMF) calculation. Missing data are due to power and instrument system failure, interference of ship plume,
165 unfavorable weather condition (i. e., heavy rain), and night sailing. During the cruise of Chongming to Zhanjiang,
166 NO₂ VCDs varied from 1.05 × 10¹⁴ to 4.02 × 10¹⁶ molec.cm⁻² with an averaged value of 3.90 × 10¹⁵ molec. cm⁻². NO₂
167 VCDs varied from 1.08 × 10¹⁴ to 2.60 × 10¹⁶ molec.cm⁻² with an averaged value of 4.27 × 10¹⁵ molec. cm⁻² from
168 Zhanjiang to Qingdao. From Chongming to Zhanjiang, HONO VCDs varied from 1.00 × 10¹⁴ to 2.58 × 10¹⁵ molec.
169 cm⁻² with a mean value of 2.39 × 10¹⁴ molec. cm⁻². From Zhanjiang to Qingdao, HONO VCDs varied from 1.01 × 10¹⁴
170 to 2.61 × 10¹⁵ molec. cm⁻² with a mean value of 2.74 × 10¹⁴ molec. cm⁻².

171 Figure 2 showed the spatial distribution of NO₂ and HONO VCDs over the marginal seas of China. It should be noted
172 that five elevated tropospheric NO₂ VCDs hot spots were observed during the whole campaign, i.e., the coastal areas
173 of Yangtze River Delta, Taiwan straits, Guangzhou-Hong Kong-Macao Greater Bay areas, Zhanjiang Port, and
174 Qingdao port. In the coastal areas of Yangtze River Delta, the hot spots were mainly distributed in the Yangtze River
175 estuary, Hangzhou Bay, Ningbo port, Taizhou port, and Wenzhou port. These areas are mostly important shipping
176 channels or shipping ports, and are great NO₂ emission sources. The averaged NO₂ VCDs in above five areas reached
177 1.07 × 10¹⁶, 1.30 × 10¹⁶, 7.27 × 10¹⁵, 5.34 × 10¹⁵, and 3.12 × 10¹⁵ molec. cm⁻², respectively. HONO exhibited similar
178 spatial distribution characteristics as NO₂, and the averaged HONO VCDs in above five hot-spot areas reached 1.01 ×
179 10¹⁵, 7.91 × 10¹⁴, 6.02 × 10¹⁴, 5.36 × 10¹⁴, and 5.17 × 10¹⁴ molec. cm⁻², respectively. It indicates that NO₂ is an
180 important precursor of HONO. Previous studies have reported that HONO can produced from NO₂ through
181 heterogeneous reaction on the surface of aerosol and sea (Yang et al., 2021). However, there are obvious differences
182 in the concentration distribution of HONO and NO₂ in the southeast coastal area of Jiangsu (from Qidong to Dongtai).
183 In this area, NO₂ showed a higher concentration (1.66 × 10¹⁶ molec. cm⁻², 4 times higher than the mean NO₂ VCD),
184 while HONO showed a lower concentration (2.06 × 10¹⁴ molec. cm⁻², ~80% of the mean HONO VCD). It might be
185 the fresh ship emission plume on the route enhancing the NO₂ concentration and HONO has not been fully formed
186 from NO₂ heterogeneous reaction in time, due to the observations from ship-based MAX-DOAS are instantaneous.
187 On the other hand, the solar radiation intensity in this day (12 May, 2018) was significantly lower than other days (Fig.
188 S2), and this weather condition was not conducive to the HONO formation through the heterogeneous reaction of
189 NO₂.

190 The surface concentration of NO₂ and HONO were extracted from their corresponding vertical profiles. As shown in
191 Figure 3, the total averaged near-surface NO₂ concentrations under viewing sea and viewing land conditions were
192 8.46 and 11.31 ppb, respectively. The total averaged near-surface HONO concentrations were 0.23 and 0.27 ppb
193 under viewing sea and viewing land conditions. Previous studies reported that vehicle and ship emissions were the
194 main HONO primary sources on land and sea, respectively, and NO₂ heterogeneous reaction on the surfaces of ground,
195 sea, vegetation and aerosol were the HONO important secondary sources (Liu et al., 2021). They also found the
196 surface HONO concentration under sea case was lower than that under land case, especially in the morning and
197 evening (Yang et al., 2021). Figure 4 shows the time series of AOD, the surface concentrations of NO₂ and HONO,
198 and the surface HONO/NO₂ during the whole campaign. We could find the time series of AOD and NO₂ are similar.
199 The high AOD and NO₂ usually appeared in busy shipping channels and ports, and the obvious high-value areas are
200 the coast of the Yangtze River Delta, the Taiwan Strait, Xiamen port, Zhanjiang port and Qingdao port (with a 1.28
201 mean AOD and a 18.90 ppb mean NO₂). HONO always appeared under high AOD and NO₂ conditions, however,

202 high AOD and NO₂ were not necessarily accompanied with high production rate of HONO. This is because the
203 heterogeneous formation of HONO requires suitable meteorological conditions (i.e., RH and temperature) in addition
204 to its precursor (NO₂) and the reaction surface (aerosol) (Liu et al., 2019). The high HONO/NO₂ values were found on
205 02, 13 and 14 May with an average value of 0.45 during the whole campaign. Moreover, we found the high values of
206 HONO/NO₂ always appeared from 11:00 to 14:00 during a whole day. That is due to the high production rate of
207 HONO and the high photolysis rate of NO₂ during noontime.

208 3.2 The relationship between HONO/NO₂ with RH, Temperature and aerosol in land and sea

209 In order to fully understand the differences of the impacts of RH, temperature and aerosol on the HONO secondary
210 formation in land and sea conditions, the Chinese Academy of Meteorological Sciences (CAMS) and Southern
211 University of Science and Technology (SUST) MAX-DOAS stations were selected as inland and coastal areas for
212 analysis, respectively. Sun et al. (2020) reported that HONO concentrations could increase up to 40–100% over the
213 navigation areas, and Huang et al. (2017) reported vehicle exhaust could contribute to ~12–49% of the atmospheric
214 HONO budget. Since the direct emissions of the measurement ship have been removed before data analysis, the
215 primary source of HONO during the whole campaign was mainly from the direct emissions of cargo ships. We used
216 an averaged $0.46 \pm 0.31\%$ emission ratio of $\Delta HONO / \Delta NO_x$ in this study referring to Sun et al. (2020) to understand
217 the primary source of HONO on the sea surface during the campaign. The NO was measured using in situ instrument,
218 and sea-surface NO₂ was extracted from the retrieved NO₂ vertical profiles (NO_x = NO + NO₂). In addition, the
219 calculation method of emission ratios of $\Delta HONO / \Delta NO_x$ in CAMS and SUST was referred to Xu et al. (2015) and
220 Xing et al. (2021). The averaged emission ratios in CAMS and SUST were $0.82 \pm 0.34\%$ and $0.79 \pm 0.31\%$,
221 respectively. The direct emissions have been deduced in the following study of the secondary formation of HONO.
222 Moreover, the secondary formation pathway of HONO are believed mainly from the heterogeneous reaction of NO₂
223 on the surface. The linear regression between HONO and NO₂ in land and static sea scenarios is shown in Figure 5.
224 We found the fitting slopes in static sea scenes was ~8–10 times larger than that in land scenes, especially on the static
225 condition viewing sea (slope ≈ 0.06). The correlation coefficients (R) in inland and static sea scenes were all > 0.62 ,
226 except in SUST (R = 0.58). That indicates the formation rate of secondary HONO from NO₂ heterogeneous reaction
227 in static sea scenes might be faster than that in land scenes.

228 3.2.1 RH dependence on HONO formation

229 The scatter plots of HONO/NO₂ against RH in different land and sea conditions are illustrated in Figure 6. In order to
230 eliminate the influence of other factors, the average of six highest HONO/NO₂ in each 10% RH interval is calculated.
231 We found the RH turning points in inland (CAMS) and coastal (SUST) cases are all ~65% (60–70%). The
232 HONO/NO₂ increases along with RH when RH is less than 65%, and the HONO/NO₂ will decrease when RH is larger
233 than 65%. That means it contributes to the HONO formation from the heterogeneous reaction of NO₂ on wet surfaces
234 with the gradual increase of RH until 65%. The decrease of HONO/NO₂ with RH larger than 65% is presumably due
235 to the efficient uptake of HONO on wet surfaces and the wet surfaces being less accessible or less reactive to NO₂
236 when RH being larger than 65% (Liu et al., 2019). However, two turning peaks of RH were found in sea cases. The
237 first RH turning peak occurred in ~60%, which is the similar with that under inland and coastal cases. While another
238 RH turning peak appeared in ~85% (80–90%). That means high RH also could increase the HONO formation in sea
239 cases. In addition, the HONO/NO₂ decreased sharply when RH was larger than 95%, because the reaction surface will
240 asymptotically approach a water droplet state to limit the formation of HONO with RH larger than 95%.

241 3.2.2 Temperature dependence on HONO formation

242 The scatter plots of HONO/NO₂ against temperature in different land and sea conditions are shown in Figure 7. To
243 eliminate the influence of other factors, the average of the six highest HONO/NO₂ values in each 5°C temperature
244 interval is calculated. In inland condition (CAMS), the HONO/NO₂ decrease along with the increase of temperature,
245 and the HONO/NO₂ peak values appeared on the temperature being ~12.5°C. However, we found the HONO/NO₂
246 increase along with increasing temperature, and the peak values of HONO/NO₂ appeared with ~31.5°C temperature
247 in coastal condition (SUST). That indicates the HONO formation from NO₂ heterogeneous reaction will be
248 accelerated under lower and higher temperature in inland and coastal conditions, respectively. In sea condition, the
249 HONO/NO₂ increase along with the increase of temperature with a peak value under ~25.0°C temperature when the
250 atmospheric temperature was larger than 18.0°C, simultaneously, a ~1.9 averaged HONO/NO₂ high value was found
251 under ~15.0°C (14.0–17.0°C) temperature. Moreover, we found that the appearance of HONO/NO₂ peak values under
252 lower temperature (14.0–17.0°C) usually accompanied by landing wind. Wen et al. (2019) also reported that relatively
253 high temperature could contribute to the formation of HONO in sea condition.

254 3.2.3 Impact of aerosol on HONO formation

255 In order to further understand the HONO formation from NO₂ heterogeneous reaction on aerosol surface, several
256 correlation analyses were carried out. As shown in Figure 8, the linear regression plots between HONO and aerosol,

257 and between HONO/NO₂ and aerosol in land and sea conditions were performed. It was found that the correlation
258 coefficient (R) between HONO and aerosol varied in the order of coastal (0.55) > sea (0.51) > inland (0.14). In
259 addition, the fitting slopes under coastal and sea conditions (0.07) are about 2.3 times larger than that under inland
260 condition (0.03). That means the ground surface maybe more important than aerosol surface during the process of
261 HONO formed from NO₂ heterogeneous reaction in the ground surface layer of inland. In coastal and sea conditions,
262 the aerosol and sea are all important to provide heterogeneous reaction surface for NO₂ to form HONO (Cui et al.,
263 2019; Wen et al., 2019; Yang et al., 2021). In addition, we found the averaged values of HONO/NO₂ are 0.011, 0.014
264 and 0.008 when aerosol extinctions are 0-0.3, 0.3-0.6, and 0.6-0.9 km⁻¹ in inland case, respectively. The high values of
265 HONO/NO₂ are mainly under aerosol extinction being less than 1.0 km⁻¹ with averaged values of 0.16 and 0.32 in
266 coastal and sea cases, respectively. It indicates that aerosol surface plays a more important role to form HONO
267 through NO₂ heterogeneous reaction in sea condition than that in land condition.

268 3.3 Vertical distributions of HONO/NO₂ under different aerosol condition in land and sea

269 In order to further investigate the height dependence of HONO/NO₂ under land and sea conditions, two cases in Pearl
270 River Delta (PRD) were selected from the whole campaign. As shown in Figure 9, “A” and “B” were under similar
271 aerosol level (the extinction coefficients in surface layer being 0.45-0.60 km⁻¹) and vertical distribution structure, and
272 were all observed from 10:00 to 11:00. The instrument viewed sea accompanied with sea wind in “A” named sea
273 scene, and the instrument viewed land accompanied with land wind in “B” named land scene. The NO₂ in sea and
274 land scenes have a similar vertical structure, and the NO₂ concentration in land scene are larger than that in sea scene
275 except on the surface layer. The HONO have the same vertical distribution structure in above two scenes, and the
276 HONO concentration in land scene always larger than that in sea scene. In Figure 9(e), we found that HONO/NO₂
277 under 0-400 m in land scene is higher than that in sea scene, however, the HONO/NO₂ values are obviously lower in
278 land scene than that in sea scene above 400 m. Moreover, the growth rate of HONO/NO₂ with the increase of height
279 in sea scene is significantly faster than that in land scene above 400 m. It indicates the generation rates of HONO
280 sourced from NO₂ heterogeneous reaction on aerosol surface in sea scene is larger than that in land scene above 400
281 m. Under 400 m, the HONO generation rates in land scene is larger than that in sea scene.

282 In addition, we selected inland cases (CAMS) to learn the difference of height dependence of HONO/NO₂ compared
283 with scenes. As shown in Figure 10, the sea and inland scenes have the similar aerosol levels (low aerosol level: < 0.2
284 km⁻¹) and vertical structure. Moreover, the NO₂ and HONO in sea and inland scenes have the similar vertical structure,
285 but their concentrations in sea scene are all larger than that in inland scene. In Figure 10(d), we could find the
286 HONO/NO₂ in sea scene is obviously larger than that in inland scene above 400 m. The HONO/NO₂ in sea scene is
287 about 4.5 times larger than that in inland scene especially above 600 m. As shown in Figure 11, the aerosols under sea
288 and inland scenes are also with the similar extinction levels (relatively high level: ~0.8 km⁻¹) and vertical structure.
289 The NO₂ concentration in sea scene is higher than that in inland scene with a similar vertical structure. The HONO
290 concentration in sea scene is lower than that in inland scene under 400 m, while it in sea scene is larger than that in
291 inland scene above 400 m. In Figure 11 (d), we found the HONO/NO₂ in inland scene is larger than that in sea scene
292 under 600 m, while the HONO/NO₂ in sea scene is about 2 times larger than that in inland scene above 600 m. Above
293 all cases indicate that the HONO generation rate from NO₂ heterogeneous reaction in sea scene is larger than that in
294 inland scene in higher atmospheric layers above 400-600 m. The high-altitude (> 400-600 m) atmospheric parameters
295 in sea scene are more conducive to promote the HONO formation through the heterogeneous reaction of NO₂.

296 3.4 Case study

297 3.4.1 20 April: A typical transport event

298 As shown in Figure 12, the aerosol mainly distributed in 0-200 m with a mean extinction coefficient larger than 0.74
299 km⁻¹. NO₂ was mainly distributed near the ground surface with a mean concentration 28.54 ppb before 13:20. The
300 NO₂ during this period might come from local ship emissions, due to this area is a main shipping channels. From
301 14:25 to 17:10, a high-concentration NO₂ air mass (averaged 13.29 ppb) was found at ~2.0 km. In order to understand
302 their source of this high-altitude NO₂ air mass, we further investigated the possible influence of transport by using the
303 backward trajectories. We calculated 24 h backward trajectories of air masses at 500, 1000 and 2000 m using
304 HYSPLIT (Hybrid Single-Particle Lagrangian Integrated Trajectory) developed by the National Oceanic and
305 Atmospheric Administration Air Resource Laboratory (NOAA-ARL). The meteorological data with a 1°×1° spatial
306 resolution and 24 layers were collected from the Global Data Assimilation System (GDAS). In Figure 13, we found
307 that the dominant wind direction during this period was southeast at all 500, 1000 and 2000 m. The transport of air
308 masses carried NO₂ emitted by ships in Ningbo and Zhoushan ports, to main cargo ports of China, to Shanghai.
309 Moreover, the concentration of NO₂ was low (averaged 2.32 ppb) near the ground surface from 14:25 to 17:10. As
310 shown in Figure 12 (e) and (g), a low pressure (< 1020 hPa), north dominant wind direction with the wind speed > 12
311 m/s appeared at ground surface during this period. That means the clean air from north reduced the local surface NO₂.
312 The HONO was mainly distributed near the surface with a mean concentration of 0.07 ppb, and two peaks were found
313 at the early morning (averaged 0.15 ppb) and 12:15 (averaged 0.11 ppb), respectively. The relatively high
314 concentration of HONO appeared in the early morning was accumulated with the stabilization of boundary layer and

315 attenuation of solar radiation after the sunset the day before (Xing et al., 2021). The HONO peak appeared at 12:15
316 might source from the heterogeneous reaction of NO₂ on the aerosol surface under a ~80% RH, a 18.5°C temperature,
317 and a 1×10^3 W/m² SRI conditions.

318 **3.4.2 28 April: A typical event of HONO produced from NO₂ heterogeneous reaction**

319 The measurement ship moored at Xiamen port on 28 April. This is a typical port observation case. As shown in Figure
320 14, we found there are two peaks for aerosol and NO₂ at 09:00-11:00 and 14:00-16:00 (averaged aerosol extinction
321 coefficient > 0.8 km⁻¹, averaged NO₂ concentration > 12.0 ppb), respectively. NO₂ was mainly distributed near the sea
322 surface layer 0-200 m, and there was a high-concentration NO₂ air mass being found in 1.0-2.0 km during
323 13:00-14:00 due to the short distance transport of NO₂ emitted from ships in Xiamen port. However, aerosol appeared
324 in the range of 0.0-2.0 km during 09:00-11:00 and 14:00-16:00. In Figure 14 (g), we found the wind speeds in above
325 two peak periods were obviously higher than other periods. In 09:00-11:00, the wind speed was ~5.0 m/s with a
326 northwest dominant direction (urban), and the wind speed was ~6.0 m/s with a southeast dominant direction (port
327 gateway) during 14:00-16:00. That indicates the short-distance high-altitude transport caused the appearance of
328 high-extinction aerosol mass during above two periods.

329 Moreover, we found the high-concentration HONO only appeared at 14:00-16:00 with a 0.57 ppb averaged
330 concentration under 0.9 km, while it was only about 0.14 ppb during 09:00-11:00 period. The higher RH and
331 temperature (Tem) (RH: ~75.0%, Tem: 23.7°C) at 14:00-16:00 than that (RH: ~67.6%, Tem: 23.1°C) at 09:00-11:00
332 (Figure 14 (d)-(e)) promoted the HONO formation from the heterogeneous reaction of NO₂ on the aerosol surface
333 during 14:00-16:00. On the other hand, the solar radiation intensity (SRI) (~600 W/m²) at 09:00-11:00 was obviously
334 larger than that (~250 W/m²) at 14:00-16:00 (Figure 14 (f)). The higher SRI accelerated the photolysis of HONO
335 during 09:00-11:00 period. Therefore, the lower formation rate and higher photolysis rate led to a significantly
336 lower HONO concentration at 09:00-11:00 than that at 14:00-16:00.

337 **3.4.3 03 May: A typical event with unknown HONO source**

338 The measurement ship carried out observation in the sea area near Zhanjiang on 03 May, 2018. As shown in Figure 15,
339 we found there was an obvious sinking process for aerosol from ~1.0 km during 09:00-16:00, and eventually
340 accumulated near the sea surface with a high extinction coefficient > 0.92 km⁻¹. The NO₂ was mainly concentrated
341 near the sea surface layer (0-400 m) with an averaged concentration of 8.93 ppb from 08:00 to 09:00. Afterwards,
342 with the rise the planetary boundary layer (PBL) height after sunrise, NO₂ was gradually mixed and spread throughout
343 the PBL from 09:00 to 13:00. During this period, it is accompanied by the increase of the NO₂ concentration
344 (averaged 11.2 ppb) under PBL. It is due to the contribution of ship emissions near the sea surface. On the other hand,
345 the regional transport of NO₂ from land also increased the NO₂ concentration in this sea area, with the wind speed
346 increase from 2.5 to 7.8 m/s with a north wind direction from 10:00 to 16:00 (Figure 15 (g)).

347 Several HONO peaks (> 0.2 ppb) at 0.5-1.0 km were found from 10:00 to 13:00, and the aerosol and NO₂ high values
348 were also observed at this height layer, simultaneously. That means the heterogeneous reaction of NO₂ on aerosol
349 surface is more important than that on the sea surface for HONO source under sea atmosphere. In addition, HONO
350 concentration obviously elevated after 14:00, especially during 14:00-16:00 (> 0.4 ppb). It might source from
351 heterogeneous reaction of NO₂ on the aerosol surface, under RH a being ~92.5% (Figure 15 (d)). The photolysis of
352 HONO also decreased with SRI < 150 W/m² (Figure 15 (f)) during this period. Moreover, a HONO peak (> 0.32 ppb)
353 was observed during 16:40-17:10. However, the NO₂ always kept lower concentration (< 1.5 ppb) after 16:00, the
354 temperature was lower than 17 °C (Figure 15 (e)), and it indicates the heterogeneous reaction of NO₂ being not the
355 source of this HONO peak. The wind was north dominant with an average speed at 7.8 m/s after 15:00, and it means
356 the regional transport might not be the source of this high-concentration HONO. Moreover, the SRI was lower than
357 87.5 W/m², and it shows the photolysis of nitrate aerosol also being not the source of the elevated HONO. The
358 unknown HONO source in this sea area need to be further explored.

359 **4 Summary and Conclusions**

360 Ship based MAX-DOAS observations along the marginal seas of China were performed from 19 April to 16 May
361 2018, simultaneously, two ground based MAX-DOAS observations were carried out in the inland station CAMS and
362 the coastal station SUST during the same time to measure the aerosol, NO₂, and HONO vertical profiles to learn the
363 sea-land and vertical differences of NO₂ heterogeneous reaction to produce HONO. The latitude and longitude ranges
364 of the entire ship based campaign covered 21.12°N-35.89°N and 110.67°E-122.16°E, respectively. We found five hot
365 spots of tropospheric NO₂ and HONO VCDs in Yangtze River Delta, Taiwan straits, Guangzhou-Hong Kong-Macao
366 Greater Bay areas, Zhanjiang Port, and Qingdao port. The averaged values of NO₂ in above five areas were $1.07 \times$
367 10^{16} , 1.30×10^{16} , 7.27×10^{15} , 5.34×10^{15} , and 3.12×10^{15} molec. cm⁻², and the averaged HONO concentrations in
368 above five areas were 1.01×10^{15} , 7.91×10^{14} , 6.02×10^{14} , 5.36×10^{14} , and 5.17×10^{14} molec. cm⁻², respectively.
369 However, we found NO₂ showed a higher concentration (1.66×10^{16} molec. cm⁻²), while HONO showed a lower
370 concentration (2.06×10^{14} molec. cm⁻²) in the southeast coastline of Jiangsu province. Moreover, the averaged

371 near-surface NO₂ concentrations were 8.46 and 11.31 ppb, and the averaged near-surface HONO concentrations were
372 0.23 and 0.27 ppb under viewing sea and viewing land observation azimuths during the whole campaign, respectively.
373 HONO always appeared under high AOD and NO₂ conditions.
374 In order to further understand the impacts of RH, temperature, and SRI on the heterogeneous reaction of NO₂ to
375 produce HONO, the emission rates of $\Delta HONO / \Delta NO_x$ in sea, inland and coastal areas were calculated with
376 values of $0.46 \pm 0.31\%$, $0.82 \pm 0.34\%$, and $0.79 \pm 0.31\%$ to remove the primary HONO source. We found the RH
377 turning points in CAMS and SUST are all ~65% (60-70%). The HONO/NO₂ increased with increase of RH under
378 65%, and the HONO/NO₂ decreased when RH is larger than 65%. However, two turning peaks (~60% and ~85%) of
379 RH were found in sea case. That means high RH could contribute to the secondary formation of HONO in sea
380 atmosphere. Moreover, the HONO/NO₂ decreased with the increase of temperature, and with peak values on ~12.5°C
381 in CAMS, however, it increase with increasing temperature, and peaked at ~31.5°C in SUST. In sea case, the
382 HONO/NO₂ increased with the increase of temperature with a peak value on ~25.0°C under the temperature > 18.0°C,
383 simultaneously, a ~1.9 averaged HONO/NO₂ high value was found under ~15.0°C. It illustrated the high temperature
384 could promote the formation of HONO from NO₂ heterogeneous reaction in sea and coastal atmosphere. In addition,
385 the correlation analysis under different sea-land conditions told us the ground surface plays a more important role than
386 aerosol surface during the HONO formation from the heterogeneous reaction of NO₂ under inland case, while the
387 aerosol surface plays a more important role during above process under coastal and sea cases. Furthermore, we found
388 that the HONO/NO₂ in sea case is about 4.5 times larger than that in inland case above 600 m under aerosol extinction
389 coefficient ~0.2 km⁻¹, and the HONO/NO₂ in sea case is about 2 times larger than that in inland case above 600 m
390 under aerosol extinction coefficient ~0.8 km⁻¹. That means the generation rate of HONO from NO₂ heterogeneous
391 reaction in sea case is larger than that in inland CASE in higher atmospheric layers above 600 m.

496 **Table 1. Detailed information of the measurement cruise**

Cruise NO.	Periods	Measurement cruise
NO. 1	08:50 to 21:02 19 Apr.	Daishan port (30.24°N, 122.16°E) to Chongming (31.18°N, 121.82°E)
NO. 2	05:40 to 17:45 20 Apr.	Sailing around Chongming island
NO. 3	06:03 21 Apr. to 08:07 03 May	Chongming (31.18°N, 121.82°E) to Zhanjiang port (21.12°N, 110.67°E)
NO. 4	08:07 03 May to 06:52 09 May	Zhanjiang port (21.12°N, 110.67°E) to Daishan port (30.24°N, 122.16°E)
NO. 5	05:40 11 May to 05:55 14 May	Daishan port (30.24°N, 122.16°E) to Qingdao (35.89°N, 120.87°E)
NO. 6	05:55 14 May to 10:00 16 May	Qingdao (35.89°N, 120.87°E) to Daishan port (30.24°N, 122.16°E)

Table 2. Detailed retrieval settings of O₄, NO₂ and HONO.

Parameter	Data source	Fitting internals (nm)		
		O ₄	NO ₂	HONO
Wavelength range		338-370	338-370	335-373
NO ₂	298K, I ₀ -corrected, Vandaele et al. (1998)	✓	✓	✓
NO ₂	220K, I ₀ -corrected, Vandaele et al. (1998)	✓	✓	✓
O ₃	223K, I ₀ -corrected, Serdyuchenko et al. (2014)	✓	✓	✓
O ₃	243K, I ₀ -corrected, Serdyuchenko et al. (2014)	✓	✓	✓
O ₄	293K, Thalman and Volkamer (2013)	✓	✓	✓
HCHO	298K, Meller and Moortgat (2013)	✓	✓	✓
H ₂ O	HITEMP (Rothman et al. 2010)	×	×	✓
BrO	223K, Fleischmann et al. (2004)	✓	✓	✓
HONO	296K, Stutz et al. (2000)	×	×	✓
Ring	Calculated with QDOAS	✓	✓	✓
Polynomial degree		Order 5	Order 5	Order 5
Intensity offset		Constant	Constant	Constant
