

Abstract

Multiple states of woody cover under similar climate conditions are found in both conceptual models and observations. Due to the limitation of the observed woody cover data set, it is unclear whether the observed bimodality is caused by the presence of multiple stable states or is due to dynamic growth processes of vegetation. In this study, we combine a woody cover data set with an above ground biomass data set to investigate the simultaneous occurrences of savanna and forest states under different precipitation forcing. To interpret the results we use a recently developed vegetation dynamics model (the Balanced Optimality Structure Vegetation Model), in which the effect of fires is included. Our results show that bimodality also exists in above ground biomass and retrieved vegetation structure. In addition, the observed savanna distribution can be understood as derived from a stable state and a slightly drifting (transient) state, the latter having the potential to shift to the forest state. Finally, the results indicate that vegetation structure (horizontal vs. vertical leaf extent) is a crucial component for the existence of bimodality.

1 Introduction

Results from numerous conceptual models have demonstrated the possible existence of multiple stable states, corresponding to savanna and forest states, in tropical terrestrial ecosystems (Scheffer et al., 2001; Rietkerk et al., 2004; Murphy and Bowman, 2012). The simulated savanna and forest states appear to be stable as they have a recovery ability in these models when perturbed. To investigate the presence of multiple stable states in observations Hirota et al. (2011); Staver et al. (2011b) used the global tropical tree cover product from MODIS (Hansen et al., 2003). In the density distribution of woody cover in tropical regions two peaks could be distinguished. One of these peaks, in the 10–50 % density range, was identified as the savanna state and the other, in the 60–80 % density range, as the forest state.

Interactive Discussion

Values of woody cover near stable states indeed have a higher probability to appear in the observed wood cover database (Van Nes et al., 2012). However, the relation between the observed density distribution and the presence of multiple stable states is complicated by the presence of transient growth processes, in particular those with a time scale extending the length of the data set. Bimodality of observed woody cover can also be caused by logistic growth rates that are randomly distributed over all age classes. A similar phenomenon is the observed bimodality of soil moisture, which is thought to be caused by the seasonal forcing, and not the soil moisture-precipitation feedback (Teuling et al., 2005). Determining whether multiple states are the correct interpretation of the observed density distribution of woody cover is crucial to the prediction of critical transitions (Scheffer et al., 2009).

In this paper, we revisit the issue of bimodality in tropical terrestrial ecosystems and focus on the effects of transient processes on the peaks in the density distribution of woody cover. The MODIS woody cover database is not sufficient to detect transient growth processes because one cannot retrieve vegetation developmental age from it. Even though woody cover increases with vegetation age, it is also significantly influenced by spatial structures of vegetation (Archibald and Bond, 2003; Yin et al., 2013). To distinguish transient growth processes from stable equilibria we use an additional and independent data set, the Above Ground Biomass (AGB) data set (Baccini et al., 2008). By combining the observed AGB and woody cover data, we are able to retrieve the vegetation structure and derive an estimation of the development change in stage of the woody cover.

In addition to this data analyses, we also consider the role of transient processes on the vegetation density in the recently developed Balanced Optimality Structure Vegetation Model (BOSVM, Yin et al., 2013). This surface water-carbon-energy balanced model was developed by integrating several existing parameterizations from widely used models (TRIFFID, Cox, 2001, LPJ, Sitch et al., 2003, TESSEL, van den Hurk et al., 2000, CHTESSEL, Boussetta et al., 2013, CLM, Oleson et al., 2004). BOSVM is able to simulate vegetation dynamics with different spatial structures. Moreover, it

Interactive Discussion

includes the interaction between vegetation and soil water, which is one of the key drivers of the bimodality (Konings et al., 2011). By using the BOSVM, we found that under water stressed conditions vegetation-soil water interactions can lead to either vegetation patches (savanna) or fully covered states (forest), which is determined by vegetation structure (Yin et al., 2013).

The new element in BOSVM introduced here is the process of fire which is considered as another important driver to the bimodality (Archibald et al., 2009; Hirota et al., 2011; Staver et al., 2011b; Mayer and Khalyani, 2011). A positive feedback of fire maintains the savanna system in areas where forest can survive (Cochrane et al., 1999; Bucini and Hanan, 2007). It reduces the forest cover and promotes grass extension, which in turn increases fire occurrence and intensity. Using this new version of BOSVM, we calculate the above ground biomass and woody cover for each specific vegetation structure under a given climate (precipitation) regime.

The structure of the paper is as follows. After the presentation of the data sets and the BOSVM in Sect. 2, we analyse the MODIS woody cover and above ground biomass datasets in Sect. 3. In this section, also the BOSVM results will be presented and compared to the observations. The sensitivity of bimodality in the model results to several crucial factors (e.g., vegetation structure, Fire Return Interval and decomposition time due to litter) is also addressed. A summary and discussion of the results is provided in Sect. 4 and we conclude in Sect. 5.

2 Data, model and methods

We are studying a mixed vegetation type where savanna and forest may coexist. The probability density function (PDF) of the observed woody cover (f_c) and above ground biomass (AGB) data can reflect whether bimodality exists. In Sect. 2.1, we introduce the data sets that we use in this study and the methods of data processing. The BOSVM model is shortly described in Sect. 2.2 with focus on the implementation of

fire processes. Finally, in Sect. 2.3, the bimodality test used for both the observations and model results is described.

2.1 Data Sets

In this work, data sets of woody cover (f_c), above ground biomass (AGB) and mean annual precipitation (MAP) are used. Our study area is the region $[20^\circ \text{ W}, 30^\circ \text{ E}] \times [5^\circ \text{ S}, 5^\circ \text{ N}]$, where the three data sets overlap. Note that in this region, the MAP is larger than 800 mm yr^{-1} , which enables forest states to survive (Sankaran et al., 2005; Yin et al., 2013).

The woody cover production (MOD44B, Hansen et al., 2003) is retrieved from seven bands of the Moderate resolution Imaging Spectroradiometer (MODIS) between October 2000 and December 2001 by using a regression tree algorithm developed by Hansen et al. (2002). The spatial resolution is 500 m. The AGB data set (averaged between 2000 and 2003) is produced by Woods Hole Research Center (Baccini et al., 2008). Nadir Bidirectional reflectance distribution function Adjusted Reflectances (NBAR) from MODIS and field measurements are used for woody plants classification and AGB estimation. The result is validated by Lidar measurement from the Geoscience Laser Altimeter System (GLAS). The spatial resolution is 1 km. The unit of AGB is $\text{Mg Biomass ha}^{-1}$ and one unit is equal to half a unit of Mg C ha^{-1} (www.whrc.org). The MAP data we used is from the AMMA Land Surface Model Intercomparison Project (ALMIP). This database provides six years (from 2002 to 2007) 3 hourly modeled forcing variables including air temperature, specific humidity, wind speed, surface pressure, precipitation rate and incoming short/long wave radiation (Boone et al., 2009). The spatial resolution is 0.5° .

Due to different spatial and temporal resolutions, the above three data sets need preprocessing before use. First, the MAP value in each grid cell of the ALMIP data is calculated by averaging over the six years of data. Potential effects of seasonality of precipitation are thus not considered here but will be addressed in a future study. Next, we resample the f_c data from 500 m to 1 km resolution by the bilinear interpolation

method to meet the spatial resolution of AGB data set. Each grid cell of the ALMIP data set (0.5° resolution) contains about 3080 grid cells of 1 × 1 km. For each available grid cell of ALMIP we randomly take 50 samples from the AGB dataset and record corresponding values of f_c . In this way, a sample set is created containing f_c , AGB, and MAP. All samples that have $f_c = 0$ or AGB = 0 are removed.

2.2 Vegetation model

The Balanced Optimality Structure Vegetation Model (BOSVM) described in Yin et al. (2013) includes vegetation spatial structure effects on the vegetation-soil water interactions. Water, energy and carbon balances are integrated by photosynthesis activity of vegetation. In this study, we include a biomass loss term due to fire in the carbon balance. The three governing equations are:

$$\frac{dW}{dt} = P - \text{Leak} - E \quad (1a)$$

$$R_n = H + IE + G \quad (1b)$$

$$\frac{dC_{\text{veg}}}{dt} = \text{NPP} \cdot \text{CA} - \text{LIT} - F(\text{FRI}) \quad (1c)$$

where W [$\text{kg H}_2\text{O m}^{-2}$] is total water stored in soil per unit area, R_n [W m^{-2}] is incoming net radiation and C_{veg} [kg C] is the total biomass, which is composed of root biomass (C_{root} [kg C]), stem biomass (C_{stem} [kg C]) and leaf biomass (C_{leaf} [kg C]).

In Eq. (1a), P [$\text{kg H}_2\text{O m}^{-2} \text{s}^{-1}$] is the precipitation rate, Leak [$\text{kg H}_2\text{O m}^{-2} \text{s}^{-1}$] is the drainage rate and E [$\text{kg H}_2\text{O m}^{-2} \text{s}^{-1}$] is the evapotranspiration rate. In Eq. (1b), H [W m^{-2}] is the sensible heat flux, IE [W m^{-2}] is the latent heat flux, G [W m^{-2}] is the soil heat flux. In Eq. (1c), NPP [$\text{kg C m}^{-2} \text{s}^{-1}$] is the net primary production; CA [m^2] is the actual crown area, LIT [$\text{kg C m}^{-2} \text{s}^{-1}$] is the decomposition due to litter and $F(\text{FRI})$ is the biomass loss term due to fire, influenced by Fire Return Interval (FRI) [yr].

The LIT is determined by total biomass and the time scale for litter decomposition (τ), according to

$$\text{LIT} = \frac{C_{\text{root}}}{\tau_{\text{root}}} + \frac{C_{\text{stem}}}{\tau_{\text{stem}}} + \frac{C_{\text{leaf}}}{\tau_{\text{leaf}}} \quad (2)$$

where τ_{root} [yr], τ_{stem} [yr] and τ_{leaf} [yr] are litter time scales of C_{root} , C_{stem} and C_{leaf} respectively. We assume equal litter time for stem and root biomass. The τ_{leaf} is kept as a constant (one year). In the following sections, τ indicates the litter time of root and stem biomass. The biomass loss due to fire is calculated as:

$$F(\text{FRI}) = \begin{cases} 0, & \text{no fire} \\ C_{\text{veg}} - C_{\text{veg}}^{\text{init}} + dt(\text{NPP} \cdot \text{CA} - \text{LIT}), & \text{fire happens} \end{cases} \quad (3)$$

where $C_{\text{veg}}^{\text{init}}$ [kgC] is the initial total biomass when the simulation starts. In the simulation process, at the end of each year a uniformly distributed ([0, 1]) random value is generated. If this random value is less than $1/\text{FRI}$, we assume that fire happens. At the next time step, C_{veg} will then be set back to its initial value $C_{\text{veg}}^{\text{init}}$. If the random value is larger than $1/\text{FRI}$, meaning no fire, there is no effect of $F(\text{FRI})$ on the biomass dynamics. Note that the value of FRI here cannot be set less than one year, otherwise $1/\text{FRI}$ is larger than 1 and fire will occur every year.

Vegetation structure is determined by two free parameters. One is the shoot-total biomass ratio (α), which represents the allocation of biomass between root and leaf biomass to balance the water uptake and photosynthesis rate with different climate regimes:

$$\alpha = \frac{C_{\text{above}}}{C_{\text{veg}}} = \frac{C_{\text{leaf}} + C_{\text{stem}}}{C_{\text{veg}}} \quad (4)$$

where C_{above} [kgC] is above ground biomass, which is equal to the sum of leaf biomass (C_{leaf} [kgC]) and stem biomass (C_{stem} [kgC]). In this study, we set $\alpha = 0.45$ as constant.

Interactive Discussion

Another parameter in BOSVM is D [-], which is defined as the ratio of the relative Leaf Area Index to the relative crown area:

$$D = \frac{\text{LAI}/\text{LAI}_{\text{ref}}}{\text{CA}/\text{CA}_{\text{ref}}} \quad (5)$$

where LAI [$\text{m}^2 \text{m}^{-2}$] is actual leaf area index, $\text{LAI}_{\text{ref}} = 6$ [$\text{m}^2 \text{m}^{-2}$] is the reference leaf area index and CA_{ref} [m^2] is a reference crown area of tree canopy, which is taken as 1 m^2 . D represents the direction of canopy growth. High D implies that vegetation canopy grows in a vertical orientation and low D implies horizontal shaped canopy. LAI and f_c are estimated by:

$$\text{LAI} = \frac{C_{\text{leaf}} \cdot \text{SLA}}{\text{CA}} \quad (6a)$$

$$f_c = \frac{\text{CA}}{\text{CA}_{\text{ref}}} (1 - e^{-k \cdot \text{LAI}}) \quad (6b)$$

where $\text{SLA} = 10 \text{ m}^2 \text{ kg C}^{-1}$ is specific leaf area; $k = 0.5$ is a constant extinction factor. Stem biomass is related to LAI as:

$$C_{\text{stem}} = a_1 \cdot \text{LAI}^{b_1} \quad (7)$$

where $a_1 = 0.65$ [kg C m^{-2}] and $b_1 = 1.667$ [-] are empirical factors (Cox, 2001). In BOSVM, we can simulate different vegetation responses to drought (Calvet, 2000; Calvet et al., 2004). In this study, we only consider the drought tolerant woody plants. More details of the BOSVM model can be found in Yin et al. (2013).

2.3 Bimodality test

To test whether bimodality exists in a probability density function determined either from observations or model results, we use the “flexmix” package in R for finite mixture

models regression (Grün and Leisch, 2007; Hirota et al., 2011). For each distribution, we assume that it is a mixture of a number of normal distributions. By a given number of clusters, the program implements the finite mixtures of regression models by the Expectation Maximization (EM) algorithm (Grün and Leisch, 2007). It is clear that the more number of clusters we hypothesize, the better fit of the model is to the distribution. To overcome this problem, three criteria are used to evaluate the fit of the model (Hirota et al., 2011): Akaike Information Criterion (AIC), Bayesian Information Criterion (BIC) and Integrated Completed Likelihood criterion (ICL). These criteria evaluate the trade-off between the goodness of fit and the complexity of the model with different parametrization. During the bimodality test, we find that the ICL is more sensitive than other criteria. Thus, only ICL results are shown in this study. For each distribution, we test one to five potential classes models according to the method in Hirota et al. (2011). The lowest value of the criteria indicates the best fit model.

3 Results

We first reconstruct vegetation structure from the observations and apply a bimodality test to the distributions of the quantities f_c , AGB, LAI and D (Sect. 3.1). Next we compare BOSVM results with the observations to understand the origin of the observed bimodality (Sect. 3.2). Finally we test the sensitivity of the BOSVM results to several parameters (FRI, D , τ) and forcing (MAP) in Sect. 3.3.

3.1 Observed vegetation structure shift with precipitation

Figure 1a and b shows the distribution of f_c and AGB values, respectively, using data from the whole research area and for all MAP values. In both distributions, we can clearly see two peaks, suggesting the coexistence of savanna (the wide peak with low f_c) and forest (the narrow peak with high f_c). To detect the two distinct states, the statistical bimodality test (Sect. 2.3) is applied to the observed f_c and AGB distributions.

savanna state is always higher than that of the forest state, indicating the higher variance of the vegetation in the savanna system.

Figure 3 shows the histogram distributions of AGB. Although bimodality is found for the whole region (Table 3), only the 800, 1200, 1400 and 2000 mm yr^{-1} precipitation regimes show bimodality in AGB. For the 1000 and 1500 mm yr^{-1} precipitation regimes, more peaks are detected. With the increase of the MAP, the savanna AGB peak increases from 1.10 to 3.56 kg C m^{-2} until 2000 mm yr^{-1} (Table 4), after which it drops to 3.12 kg C m^{-2} . However, the peak of the forest AGB increases from 5.26 to 12.40 kg C m^{-2} between 800 and 1300 mm yr^{-1} and then becomes independent to MAP. In contrast to f_c , under the three MAPs where bimodality is detected, the $R_{\mu \pm \sigma}$ of the savanna and forest states is similar.

The histograms of LAI (Fig. 4) show a clearer bimodality compared with the f_c and AGB distributions, and also display a bimodality for all precipitation regimes (Table 3). The savanna LAI peak increases from 1.27 at low MAP to 2.73 at high MAP. The forest LAI peak is about 6.0 when MAP is greater than 1000 mm yr^{-1} and then becomes independent of MAP.

Bimodality also exists in the retrieved canopy structure parameter D (Fig. 5) for all MAP values. With the increase of MAP, the savanna D peak shifts from 0.21 to 0.77, implying that the canopies of woody plants shift from horizontal to vertical structure. On the contrary, the D peak of the forest state does not shift much between 1200 and 2000 mm yr^{-1} . With lower MAP (less than 1000 mm yr^{-1}), forest structure is more horizontal. However, when using the definition of D (Eq. 5) and the average values of f_c and LAI (Table 4) to recalculate D values, we can find that the value of D for the forest state does not change much under lower MAP conditions. The failure of the bimodality test on D is caused by a high overlap between savanna and forest structures (Fig. 5). When the savanna state is dominant (MAP less than 1100 mm yr^{-1}), the peak of the forest state is too small to be detected.

3.2 Comparison of model results and observations

The BOSVM is used to generate time series of f_c and AGB. In each simulation, we choose three grid cells as climate forcing from the ALMIP data set where MAP is equal to 1000, 1200 and 1500 mm yr^{-1} . For each grid cell, we define 16 canopy structures for which D varies from 0.05 to 48.08 with a distribution determined by an inverse tangent function. The shoot-total biomass ratio is fixed as $\alpha = 0.45$. The litter time τ is equal to 30 yr. The FRI depends on MAP and has values of 30, 70 and 100 yr under 1000, 1200 and 1500 mm yr^{-1} , respectively (Pfeiffer et al., 2013).

We found that a threshold in initial total biomass exists in BOSVM determining whether the vegetation turns to bare soil or to equilibrium woody cover (Yin et al., 2013). With given MAP, D and FRI, we first calculate the survival initial biomass and then start the simulation by a slightly higher initial biomass (about 0.1 kg C higher than the survival threshold). The simulation lasts for ten thousand years and the time step is 1.5 h (5400 s). AGB and f_c values are recorded at the end of every one hundred year interval.

As the observations are snapshots that include all dynamic vegetation states, we can compare the distribution of the simulated time series with the spatial distribution of the observations to investigate the composition and stability of the observed bimodality. Note that local differences in vegetation types, soil properties and seasonalities of forcing are ignored in the simulations.

Figure 6 illustrates the simulated growth paths of vegetation with different canopy structures. Climate forcing is taken from one grid cell with MAP = 1200 mm yr^{-1} , FRI = 70 yr and $\tau = 30$ yr. Each set of coloured points indicates a specific vegetation structure (different D) and neighbouring points are hundred years apart. Both f_c and AGB increase with the growth of the vegetation. Fire happens randomly during the growth process and the probability depends on the value of FRI. Once fire happens, biomass will be set back to its initial value and regrow. Five samples of fire events are chosen and plotted (flames in Fig. 6), and the arrow illustrates how AGB decreases

Interactive Discussion

after a fire. The distance between two neighbouring points in Fig. 6 is a measure for the growth rate at corresponding stages.

From Fig. 6, we find that the relation between AGB and f_c is fixed once D is given. With the same AGB, vegetation with higher D has lower f_c , suggesting a more vertical structure according to Eqs. (5) and (8). The distance between neighbouring points is larger in the intermediate state than near the initial or the equilibrium state (the maximum AGB), implying that the vegetation growth rate is higher at intermediate values of f_c and AGB. Hence, in the observations there may be a bias in values at initial and equilibrium state as less samples exist at the intermediate state, which might contribute to the observed bimodality.

In Figs. 7 to 9, we compare the simulated results with observed data for three different precipitation regimes. For each figure, points in the left bottom panel are from the dataset of observations. Curves are simulated AGB and f_c from BOSVM, and each curve represents a specific canopy structure. The left top and right bottom panels display distributions of observed AGB and f_c respectively. For the chosen values of D , the model calculated distributions of AGB and f_c are plotted as curves in left top and right bottom panel respectively.

When $MAP = 1000 \text{ mm yr}^{-1}$ (Fig. 7), a high density of observed samples appears at low AGB and low f_c . The model shows that vegetation growth rates near the initial survival threshold and near the equilibrium value are relatively slower than that in the intermediate states (Fig. 6). In the density distributions of the simulated results, one peak (corresponding to the savanna state) is near the survival threshold while another (corresponding to the forest state) is located around the equilibrium state for all values of D . The model matches the observations reasonably well for relatively small values of D indicating a more horizontal shaped canopy. Although the forest state (high AGB and high f_c) can exist in this regime, it is rare and the model results indicate that this is due to the high fire frequency. The AGB of this forest state shows more variance than its woody cover f_c values in particular in the range of $AGB > 10 \text{ kg C m}^{-2}$ and $f_c > 0.6$.

Interactive Discussion

The bimodality is more apparent when $\text{MAP} = 1200 \text{ mm yr}^{-1}$ as shown in Fig. 8. Increased precipitation reinforces vegetation growth rate and limits fire occurrence, which in turn increases the probability of forest appearance. The model data for intermediate values of D ($= 1.40$) fit the observations best. Note that woody plants with high f_c (greater than 0.6) and low AGB (less than 10 kg C m^{-2}) are grouped in the forest state based on only f_c values. Woody plants with low f_c (less than 0.6) and high AGB (greater than 5 kg C m^{-2}) would be grouped in the savanna state based on only f_c values. However, both of these groups likely are intermediate (transient) states between the savanna and forest state. With the availability of both woody cover and AGB data, these intermediate states can be nicely distinguished.

Fire is rare when $\text{MAP} = 1500 \text{ mm yr}^{-1}$, leading to a high proportion of forest (Fig. 9). However, low f_c states still exists. Under this regime, the AGB distribution shows a more clear bimodality than the f_c distribution. Model results fit the observations best for similar values of D as for $\text{MAP} = 1200 \text{ mm yr}^{-1}$.

In summary, from Figs. 7 to 9 we find that the distribution of the savanna state is not only caused by the low growth rate of vegetation near the initial value, but also contains signatures of equilibrium states. The model results suggest that the savanna state is composed of three clusters:

- (i) Cluster H-I: vegetation near its initial state with a dominantly horizontal structure.
- (ii) Cluster V-I: vegetation near its initial state with a dominantly vertical structure.
- (iii) Cluster V-E: vegetation near its equilibrium state with a dominantly vertical structure.

The forest state is mainly composed of one cluster:

- (iv) Cluster H-E: vegetation with a dominant horizontal structure near its equilibrium state.

Both H-I and V-I clusters are transient and have the potential to increase f_c and AGB. From these only members of the H-I cluster can develop into forest states. Members

from the V-E clusters are stationary and can be reached from members of the V-I cluster.

3.3 Sensitivity analysis of model results

In the previous section, we found that the simulated bimodality is significantly influenced by vegetation canopy structure parameter, and FRI. Moreover, both litter time and MAP have effects on the vegetation survival threshold and the equilibrium state, which in turn influences the bimodality. In this section, we analyse the sensitivity of the simulated bimodality to FRI, D , τ and MAP.

To quantify the sensitivities of the simulated bimodality to FRI, D , τ and MAP, we define the reference case as in the previous section (FRI = 50 yr, $D = 0.5$, $\tau = 30$ yr, MAP = 1200 mm yr⁻¹) and vary the values of each variable FRI, τ , D and MAP, where here FRI is considered independent from MAP. All simulations last for ten thousand years and the time series of f_c are recorded. Figure 10 summarizes the findings. We use three measures to discuss this sensitivity: (C1) the ratio of the maximum density of the forest peak to that of the savanna peak, (C2) the distance between the two density peaks, and (C3) the horizontal shift in f_c of the peaks, where a positive shift is to higher f_c .

Figure 10a illustrates the effect of FRI to the simulated bimodality. FRI is an external factor that cannot affect survival threshold and equilibrium biomass for specific vegetation structure, implying that it has no impact on (C2) and (C3). However, FRI determines the frequency of fire occurrence and a larger values of FRI implies less fire occurrences and hence lead to a higher peak of the forest state and a lower one of the savanna state.

Figure 10b displays how the simulated f_c bimodality is influenced by D . D shifts the position of the two f_c peaks to lower values (C3). However, the magnitude of the impact depends on the value of D . The position of the savanna peak is more sensitive to D when D is low. On the contrary, D influences the position of the forest peak more significantly when D is high. The interpretation is that the survival threshold of vegetation

with a horizontal structure, which determines the position of the savanna peak, is more sensitive to climate variation than that of vegetation with a vertical structure. On the other hand, the equilibrium biomass with a dominant vertical structure is more sensitive to climate variation than that with a dominant horizontal structure. Moreover, the equilibrium biomass drops faster than the survival threshold with an increase of D . This implies that the distance between the savanna and forest peak, measure (C2), decreases with increasing D . For vegetation with larger D , it takes less time for f_c to increase from the initial value to equilibrium, which leads to a higher peak of the forest state (measure C1).

Figure 10c presents the effect of τ to the bimodality in the f_c distribution. The parameter τ has a positive and a negative impact on the equilibrium biomass and the survival threshold, respectively. Thus, the increase of τ extends the distance between the savanna and the forest peak (C2). Moreover, high τ means low biomass loss, promoting biomass growth rate, which consequently leads to an increase in the density of the forest state (C1). Finally, an increasing value of MAP leads to a decline of survival threshold and rise of equilibrium biomass (Fig. 10d) and leads to a largest distance between the peaks (C2). Higher MAP values also reinforce annual growth speed leading to a larger forest peak (C1).

The impacts of the four variables on the three criteria are summarized in Table 5. MAP and τ have the same type of impacts on bimodality. When only considering MAP and τ in this bimodality study, the relation between C1 and C2 will be uniquely positive, which cannot represent the complexity of woody cover. By adding FRI, we are able to simulate the relative magnitude of the peaks (C1) which coincides with the character of the bimodality of the observed vegetation structures. Furthermore, since only D affects the horizontal shift of the two peaks (C3), the canopy structure is an important variable to quantify the alternative states of woody cover.

4 Summary and discussion

The main aim of this study is to understand the vegetation dynamics behind the observed woody cover bimodality in West Africa. We have shown that the observed bimodality originates from both equilibrium states and transient growth processes of vegetation and discuss this result in the context of the available literature.

In the work of Hirota et al. (2011) and Staver et al. (2011b), the global woody cover product (Hansen et al., 2003) is used to understand alternative stable states across a gradient of mean annual precipitation. In our study, we combined this woody cover dataset with another independent above ground biomass data set (Baccini et al., 2008), from which we can calculate the vegetation structure. Our results show a clear bimodality in forest cover, above ground biomass, and retrieved LAI in West Africa (Figs. 1 to 5). By including the AGB, we think we have a better way of expressing bimodalities in vegetation structures leading from low to high cover, and low to high biomass. Our results show that both the individual density distributions of f_c and AGB may underestimate the proportion of the intermediate states between savanna and forest (Figs. 7 to 9).

Our new vegetation structure database also shows significant alternative states and is used to answer if and how vegetation structure shifts with climate regime (Figs. 1d and 5). We found that in the forest state, the values of f_c and AGB are independent of MAP and therefore do not shift with climate regime. In addition, the structure of the forest state is stable and independent of MAP. However, the savanna structure shifts with increasing MAP from horizontal to vertical structure with a large variation in both f_c and AGB, illustrating the complex vegetation dynamics of the savanna system.

To understand the shifts in vegetation structures, we used the BOSVM model (Yin et al., 2013). From the model results we found that the savanna state might be composed of three clusters (H-I, V-I and V-E) while the forest state only contains one cluster (H-E). The H-I and V-I savanna members include saplings like those described in Baukena and Provenzale (2008) and Staver et al. (2011a), which have potential for growth

Interactive Discussion

and are in general non-stationary. The V-E savanna cluster contains adult trees that already approach their equilibrium states. The H-I savanna members have the potential to shift to the forest state. On the contrary, the members of the V-I savanna cluster can only develop into ones of the V-E savanna cluster.

5 From this analysis we can understand why the savanna state has a higher variation in f_c compared to the forest state (Table 4) and how the savanna state shifts to the forest state. Moreover, with the increase of MAP, fire becomes rare, implying that more H-I savanna will develop into the forest state. Consequently, the proportion of the H-I trees in the savanna state decreases, explaining why the structure of the savanna state shifts from low D to high D with an increase of MAP.

10 Although the bimodality is successfully simulated in the BOSVM model, it is hard to approach a perfect fit between the simulation results and observations. In the BOSVM model, we did not capture the competition between grasses and woody plants, which might lead to a higher survival threshold for woody plants and avoid the underestimation of the position of the savanna f_c and AGB peaks (Figs. 7 to 9). Also, transient changes of vegetation structure parameters is not included.

15 Although the strength of our approach is that we rely on different data sources and modeling results, we still need to take these values with care. Maximum equilibrium woody cover values observed are about 0.9, while our model results give values above 0.9. The latter may actually be more realistic when compared with another woody cover product Guan et al. (2012). Recent work on the MODIS data algorithm for converting satellite measurements to tree cover has shown that the classification and regression tree (CART) method also may introduce inherent bimodalities (Hanan et al., 2013) in the data.

25 By the sensitivity analysis we summarised the impacts of the BOSVM model parameters FRI, D , τ and MAP on the three criteria of the f_c bimodality. Our results show that the bimodality is very sensitive to all variables that we tested, implying that the variation in the data set (e.g., different plant species, soil type, etc) can highly influence the observed bimodality. Meanwhile, the results also suggest that the vegetation structure

Interactive Discussion

is a crucial variable, and often is the only factor that influences the peak position of the savanna and forest state.

We found that the vegetation growth rates near the initial survival threshold and equilibrium value are relatively slower than that in the intermediate state. However, our model cannot represent the high variation of the savanna state without the effect of fire. The savanna-fire feedback is found as one of the important causes that maintains the savanna state under water sufficient conditions (Cochrane et al., 1999; Staver et al., 2011b, a; Mayer and Khalyani, 2011).

In general, FRI increases with MAP and this is sufficient to simulate the shift of the peaks in the distribution of the savanna and the forest state. However, due to the use of a uniform FRI defined for all vegetation structures under the same MAP, results show an overestimation of AGB for vertical structure vegetation (lines with $D > 2.0$ in Figs. 7 to 9). This indicates that there might be a relation between FRI and vegetation structures, as has been suggested by Archibald et al. (2009). The vertical structure vegetation has a smaller f_c . This can cause a high grass cover and sufficient grass fuel for fire. As grass fuel is a necessary condition for fire spread (Pfeiffer et al., 2013), we guess that the vertical structure vegetation might have a low FRI. Thus, the vegetation structure parameter D affects the value of FRI. Uncertainties in FRI also can be caused by rainfall seasonality, which we did not include in the model. A constant MAP regime can mean total different climates and FRI (e.g., different lengths of dry season (Staver et al., 2011b)) and this can only be studied by taking additional climatic forcing variables into account in the model.

5 Conclusions

Our main conclusions from this study are the following. First, by using the woody cover and above ground biomass data sets, we found that bimodality also exists in retrieved vegetation canopy structure and Leaf Area Index. The savanna state shifts from horizontal structure to vertical structure with the increase of the mean annual precipitation.

Bimodality of woody cover and biomass

Z. Yin et al.

Second, by comparing the model results with the observations, we found that the observed bimodality not only originates from bistable states of forest and savanna, but also from transient vegetation growth processes. The observed savanna state is composed of horizontal vegetation near its initial state, vertical vegetation near its initial state and vertical vegetation near its equilibrium state. This explains why the observed savanna state shifts from horizontal to vertical structure with an increase of mean annual precipitation.

Bimodality of woody cover and biomass

Z. Yin et al.

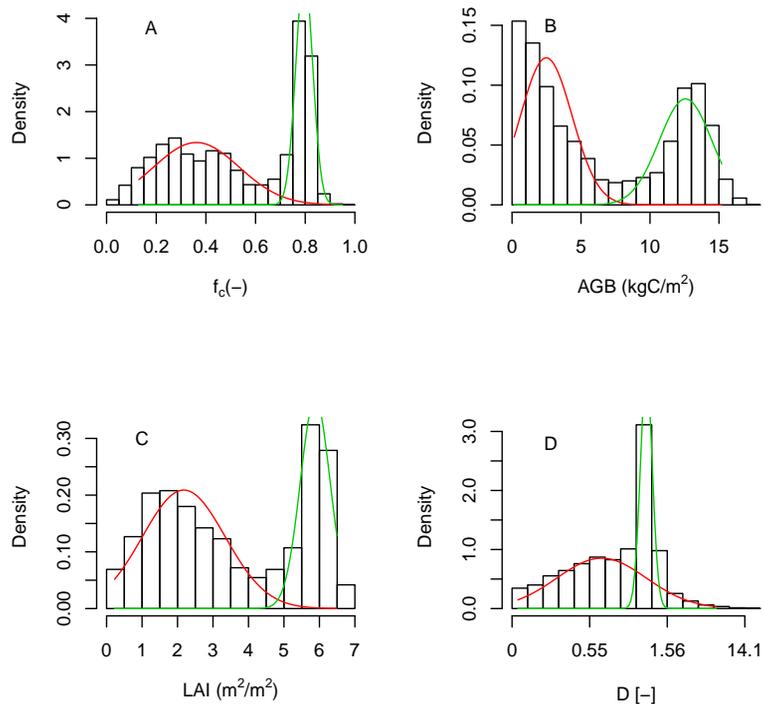

Fig. 1. Histograms of observed (or derived) f_c , AGB, LAI and D in the West Africa. LAI and D are derived from observed f_c and AGB according to Eqs. (5), (6b) and (8). Red and green curves are best fitted normal distributions by assuming two potential states (savanna and forest) exist in the observations.

Bimodality of woody cover and biomass

Z. Yin et al.

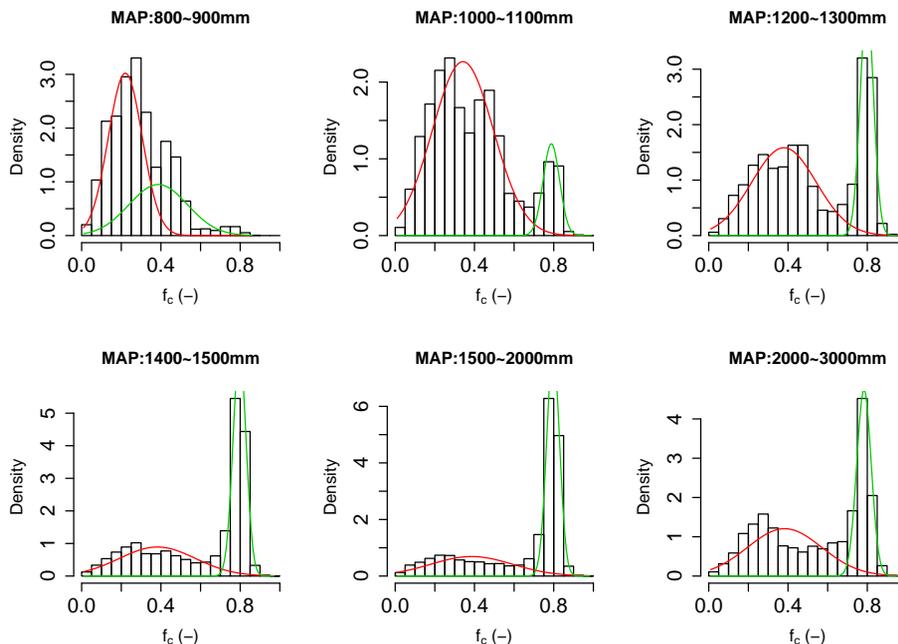

Fig. 2. Density distribution of woody cover (f_c) as shown in Fig. 1a vs. six different Mean Annual Precipitation (MAP [mm yr^{-1}]) regimes. Red and green curves are best fitted normal distributions by assuming two potential states (savanna and forest) exist in the observations.

Bimodality of woody cover and biomass

Z. Yin et al.

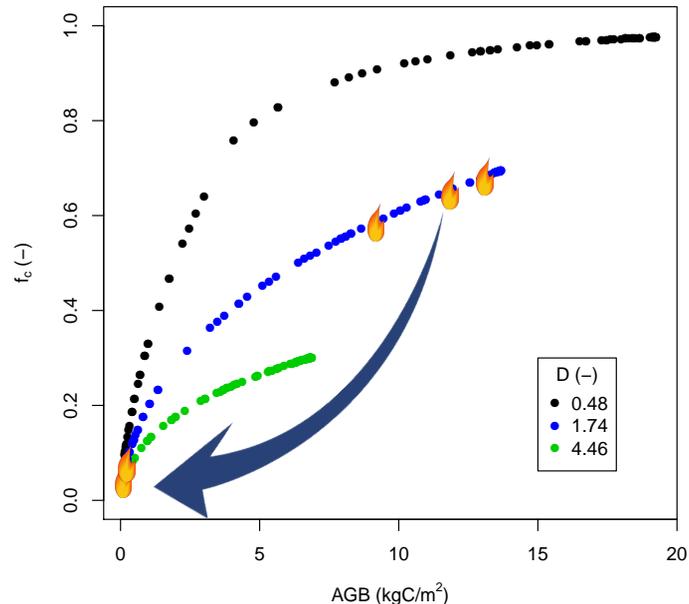

Fig. 6. Simulated transient growth path of vegetation including the effect of fire. Points indicate growth stages in a multicentennial simulation of vegetation dynamics. Different curves indicate different simulations with three chosen D values. Five samples of fire events are displayed as flames for the simulation with $D = 1.74$. When fire occurs, biomass will be removed and set back to its initial value for regrowth (the arrow). The default settings of parameters in the model are: $\tau = 30$ yr, MAP = 1200 mm yr^{-1} and FRI = 70 yr.

Bimodality of woody cover and biomass

Z. Yin et al.

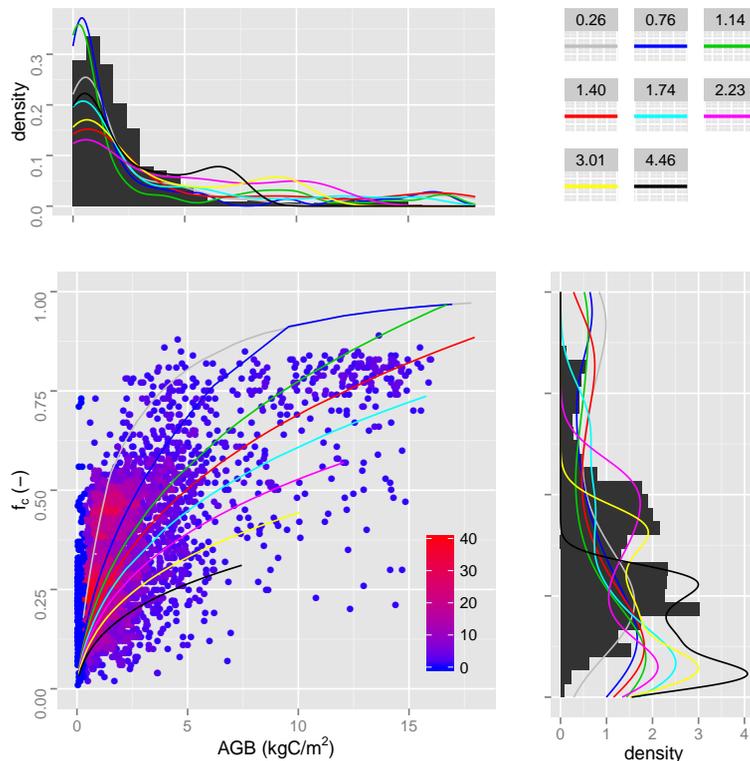

Fig. 7. Observed and simulated AGB and f_c for $\text{MAP} = 1000 \pm 50$ mm. In left bottom panel, observed samples are plotted as points. The color represents the density of samples. Lines are simulated results. Each line represents one type of canopy structure. The values of canopy structure parameter D are listed in the right top panel. Black bars in left top and bottom right panels are histograms of observed AGB and f_c , respectively. Lines in the two panels are histograms of simulated results corresponding to the same color and type lines in the left bottom panel. The value of FRI is 30 yr.
